The control of body temperature resides in the hypothalamus, which is a primitive part of the brainstem that regulates certain bodily functions, such as sleep, and that also secretes a number of neuroendocrine-releasing factors. The anterior hypothalamus contains thermosensitive neurons, whose response is affected both by the temperature of the blood and by neural connections with peripheral temperature receptors. Provided that the mechanisms governing heat production and heat loss are intact, fever results from a resetting of the thermoregulatory centre in the hypothalamus to a higher level.

The crucial step in the induction of fever appears to involve increases in the production of arachidonic acid metabolites, especially prostaglandin E_2 (PGE_2). Several different lines of evidence favour a role for PGE_2 as the neural mediator in the febrile response. Antipyretics such as ibuprofen and indomethacin are potent inhibitors of prostaglandin synthesis; cytokines such as IL-1, TNF, and IFN α all stimulate PGE_2 production from hypothalamic tissue *in vitro*; and injection of PGE_2 directly into the hypothalamus induces fever within minutes. Thus, current concepts envisage the febrile response being initiated by the production and release of endogenous pyrogens as a consequence of an infection, an inflammatory

response, or an immunologically mediated disease. The pyrogenic immunomodulators increase the level of PGE_2 in the blood, and this mediator, as well as endogenous pyrogens such as IL-1 and TNF, act on the hypothalamus to induce fever. Brain regions sensitive to the direct effect of endogenous pyrogen are restricted to regions near the organum vasculosum laminae terminalis (OVLT), whereas the nucleus Broca ventralis, preoptic area, and the anterior and ventromedial hypothalamus, are able to respond directly to injections of small doses of prostaglandins E_2 and F_2 . The ventromedial region of the hypothalamus is the area most sensitive to PGE_2 , as measured by the induction of fever in rabbits.

The different sites of action of the different mediators show that there exist two separate pathways for induction of fever. First of all, prostaglandins synthesized outside the blood-brain barrier act on multiple sites in the central nervous system to induce rapid-onset fever. In contrast, although the endogenous pyrogens have the effect of stimulating release of arachidonic acid metabolites from the hypothalamus *in vitro*, there is no direct evidence that they cross the blood-brain barrier. Their actions are probably concentrated in the vicinity of the OVLT, inducing the synthesis and release of pyrogenic prostaglandins that produce a secondary peak of fever (Figure 1). There is no evidence that prostaglandins can, of themselves, act as neurotransmitters; but they are known to increase levels of cyclic AMP, which can perform this function. Prostaglandins certainly play a central part in the induction of fever, but there exists at least one prostaglandin-independent pathway, as demonstrated by the pyrogenic action of MIP-1. The relative importance *in vivo* of

Figure 1 Schematic representation of pathways leading to the induction of fever.

each of these pathways, and their relationship, remain to be elucidated. Just as the pyrogenic cytokines can act both individually and in concert to induce fever, there similarly exists a number of endogenous antipyretics that can limit the magnitude of the febrile response, and thus prevent thermal damage. The ability of IL-1 to stimulate production of prostaglandins can be blocked by α -melanotropin-stimulating hormone; and arginine vasopressin, adrenocorticotrophic hormone and corticotropin-releasing factor can all act to alter the firing rate of neurons involved in thermoregulation.

The complexity of the pathways involved in the induction of fever are also reflected in changes in the response with age. The febrile response of kittens to endotoxin is poor during the first 6 weeks of life, and a comparable weakness in human neonates can be inferred from the failure of lymphocytes from cord blood to show enhanced T cell proliferative response at elevated temperatures. The febrile response to bacterial pyrogens also weakens with age, and micro-injection of PGE₁ into the anterior hypothalamus, as well as central administration of endogenous pyrogen, both induce responses that are significantly weaker in older animals. However, it appears that at least some of the differences can be attributed to age-related changes in vasoconstrictor responses in the peripheral vasculature.

Function of fever

The powerful mediators and complex pharmacologic pathways involved in the induction of fever indicate that the febrile process has the potential to modulate many different bodily functions. However, since fever has traditionally been associated with infection or disease, the central question is whether it is advantageous to the host. This point has been contentious, but the weight of evidence strongly suggests that fever is an adaptive response to infection.

The beneficial effects of fever are most striking in the poikilothermic vertebrates, which regulate their body temperature by behavioral means. When injected with *Aeromonas hydrophila*, a natural pathogen, the desert iguana (*Dipsosaurus dorsalis*) actively seeks to raise its body temperature, and animals permitted to maintain an elevated temperature show a marked decrease in mortality. Experiments in homeothermic animals have suggested that elevated temperatures enhance host resistance and increase survival; however, in some of these studies, growth of the organisms used was inhibited at febrile temperatures. Nevertheless, many different host defense mechanisms are modulated or augmented at temperatures corresponding to mild-to-moderate fevers

in humans. The bactericidal capacity of polymorphonuclear leukocytes is increased, as is the production of cytokines such as leukocyte migration inhibition factor (LIF) and interferon. The human lymphocyte proliferative response to polyclonal T cell mitogens and to allogeneic cells is increased; and in the mouse, both the efficiency of generation of antiviral cytotoxic T cells and the levels of activation of T helper cells in the antibody response against sheep red blood cells are enhanced. Although some of these effects can be attributed to an increase in the metabolic activity of the cells, the effect of fever on immune responses is not simple, as the responses of B cells are not affected; and at elevated temperatures, cytokines such as interferon inhibit both B and natural killer (NK) cell responses, but potentiate T cell responses. Thus, the data generally indicate that one consequence of fever may be a preferential augmentation of T cell responses, which are crucial to recovery from initial infections with viruses and bacteria.

The concept that fever is beneficial to the host is strengthened by observations that bacterial infection increases the duration of slow-wave sleep, and that activation of the immune system with accompanying fever alters sleep patterns. Many of the endogenous pyrogens, such as IL-1, TNF and the interferons, are also somnogenic, although the pathways involved in fever induction and sleep regulation are not identical. Therefore, the effect of cytokines and microbial products on hypothalamic and neural function may represent a coordinated physiologic response that allows the body to marshal all of its resources to overcome the infectious agent.

FIBROBLASTS

For R Williams, Department of Dermatology, Harvard Medical School, Massachusetts, USA

Fibroblasts are cells of mesodermal origin present in all forms of connective tissue. They are the least specialized of the connective tissue cell types. The primary role of fibroblasts is the production of proteins and polysaccharides that are secreted into the extracellular space of connective tissues to form the extracellular matrix. Appropriate combinations of these fibroblast-derived synthetic products endow each form of connective tissue with suitable physical and mechanical characteristics. The composition of the extracellular matrix produced by fibroblasts is markedly influenced by local microenvironmental factors. Some fibroblasts retain the capacity to differentiate into more specialized types of connective tissue cells, including chondrocytes, osteocytes, adipocytes and smooth muscle cells. These multipotential fibroblasts are also referred to as mesenchymal cells.

Fibroblasts also function as accessory cells in many immune and inflammatory responses. Fibroblasts can produce or respond to a wide variety of cytokines, and these mediators allow fibroblasts and leukocytes to cooperate during complex processes such as wound healing. Fibroblasts are capable of modifying their output of extracellular matrix components in response to mediators released from other cell types. Some human chronic inflammatory diseases ultimately develop into disabling fibrotic disorders, demonstrating how persistent activation of the immune system can lead to severe perturbations in fibroblast function. The constitutive production of class I major histocompatibility complex (MHC) molecules and the inducible expression of class II MHC molecules permit fibroblasts to participate in antigen presentation to T cells, although with considerably diminished efficiency relative to professional antigen-presenting cells. Cross-talk between fibroblasts and cells of the immune system occurs on a routine basis and contributes to the maintenance of homeostasis in mammalian connective tissues.

Principal fibroblast structural proteins – collagens and elastin

Production of fibrous proteins in the collagen family is a major function provided by most types of fibroblasts. At least 19 distinct types of collagen exist; they can be classified into fibrillar collagens, fibril-associated collagens (typically associated with the surface of fibrillar collagens) and network-forming collagens (involved in the formation of flat mesh-like structures such as basement membrane). Fibroblasts produce multiple types of collagen, including the fibrillar collagens I and III, which together account for 90% of the total collagen in the connective tissue of skin (Figure 1).

Type I collagen is the predominant form of collagen in skin and bone. It serves as a prototype for the structural organization of fibrillar collagens. The basic polypeptide subunit of a collagen molecule is an α chain which is composed of short globular N-terminal and C-terminal propeptides flanking a long central domain. Multiple post-translational modifications of α chains facilitate the folding of three α chains into a triple helical procollagen molecule. There are at least 25 distinct genes encoding collagen α chains scattered throughout the genome. Specific types of collagen can be assembled from trimers of the same α chain, or from two or three different α chains. For example, type I procollagen is formed by the assembly of two $\alpha 1(I)$ chains and one $\alpha 2(I)$ chain. A prominent feature of the central portion of all fibrillar collagens is the existence of three amino acid repeats with a glycine in every third position (Gly-

Figure 1 Major components of the extracellular matrix synthesized by fibroblasts within dermal connective tissue.

X-Y sequence). The X and Y positions can be filled by any amino acid, but many of the X and Y positions are occupied by prolines. During the biosynthesis of procollagen molecules, a subset of proline and lysine residues are hydroxylated to generate hydroxyproline and hydroxylysine residues. The hydroxylysines are further modified by specific glycosylation events. These specialized amino acids participate in intrachain and interchain hydrogen bonding that stabilizes the triple helix. After secretion, procollagen molecules are converted into collagens by the cleavage of N-terminal and C-terminal propeptides. Mature extracellular collagen molecules formed from three α chains associate with other collagen molecules to form collagen fibrils measuring 10–300 nm in diameter. These fibrils can in turn assemble into still larger bundles, termed collagen fibers (up to several microns in diameter).

The fibril-associated and network-forming collagens differ structurally from the fibrillar collagens. In fibril-associated collagens (e.g. types IX and XII), the triple helical stretches are interrupted with non-helical domains and the propeptides are not removed from the procollagen molecules. The resulting collagen molecules are more flexible and associate with molecules of fibrillar collagen rather than with each other. Network-forming collagens are exemplified by type IV collagen, a major component of the basement membrane. The Gly-X-Y repeats in type IV collagen are interspersed with numerous non-collagenous domains, permitting the collagen monomers to assemble into a net-like structure.

The role of fibroblasts in generating collagenous structures is not limited to synthesis of the structural proteins. Fibroblasts also have the capacity to organize and shape collagenous matrices by binding to collagen molecules through cell surface receptors and exerting mechanical force on this substrate. Through this action, fibroblasts can engineer collagen into flat sheets or rope-like strands, depending on the specific type of collagen and its tissue of origin. The major cell surface receptors for collagen on fibroblasts involved in these processes are β_1 -integrins. These integrins serve as a link between the proteins of the extracellular matrix and the intracellular actin cytoskeleton. Fibroblasts also remodel connective tissues through the production of multiple metalloproteinase enzymes that digest excess matrix material. Balanced activity of the matrix-generating synthetic machinery of fibroblasts and their metalloproteinase enzymes allows fine tuning of the extracellular matrix content within connective tissues.

Collagen fibers provide strength to connective tissues, but resiliency and flexibility are dependent on the presence of elastic fibers. Elastic fibers are made

up of a core of cross-linked tropoelastin monomers associated with microfibrillar proteins to form microfibrils measuring about 10 nm in diameter. The cross-links between individual elastin polypeptides occur via lysines that are modified and covalently linked to form the specialized amino acids desmosine and isodesmosine. The proteins associated with elastin in elastic fibers include the fibrillins (fibrillin 1 and fibrillin 2), microfibril-associated glycoprotein (MAGP) and associated microfibril protein (AMP). The microfibrillar proteins assemble in the extracellular matrix before the addition of elastin and provide the foundation on which tropoelastin molecules are subsequently deposited. The presence of elastic fibers enables tissues to recover to their original dimensions without injury after the application of a stretch force. Connective tissues rich in elastic fibers are found in the dermis of skin, the lung and the walls of large arteries.

Glycosaminoglycans and proteoglycans

Glycosaminoglycans are polysaccharide molecules that provide the extracellular matrix with additional physical properties not provided by structural proteins alone. These glycosaminoglycans include hyaluronan, chondroitin sulfate, dermatan sulfate, heparan sulfate, heparin and keratan sulfate. All of the glycosaminoglycans consist of multiple copies of a basic disaccharide repeat. Most of these molecules (with the exception of hyaluronan) are covalently linked to serine residues on core proteins through a link tetrasaccharide to form proteoglycans. Examples of proteoglycans made by fibroblasts and present in the extracellular matrix include decorin, biglycan and fibromodulin. Glycosaminoglycans and the proteoglycans they form are large negatively-charged molecules that attract cations and water molecules, leading to the formation of a hydrated gel. These molecules comprise the 'ground substance' in connective tissues that provides support while permitting cell migration and diffusion of nutrients and soluble signaling molecules within the extracellular matrix. Some glycosaminoglycans produced by fibroblasts are not secreted, but instead associate with the cell surface (e.g. CD44, betaglycan and syndecan-2).

An important additional function provided by many proteoglycans is binding of growth factors and cytokines. Attachment of these soluble mediators to proteoglycans can influence their activity in several ways. For proteins in the fibroblast growth factor (FGF) family, association with proteoglycans containing heparin or heparan sulfate greatly enhances their biological activity. Many of the chemokines, a family of structurally and genetically related cyto-

kines that are chemotactic for subsets of leukocytes, also display significant affinity for proteoglycans containing heparin and heparan sulfate. Immobilization of chemokines on to proteoglycans of the extracellular matrix allows establishment of solid-phase gradients that can direct the migration of leukocytes traveling through tissue. Other cytokines with significant affinity for heparin and heparan sulfate are granulocyte-macrophage colony-stimulating factor (GM-CSF), interleukin 3 (IL-3) and IL-7. In some cases, binding of a cytokine to proteoglycans can inhibit rather than enhance its biological activity. For example, binding of transforming growth factor β 1 (TGF β 1) to the core protein of decorin or the related proteoglycans biglycan and fibromodulin leads to a loss of TGF β 1 bioactivity.

Adhesive proteins derived from fibroblasts

Not all fibroblast products incorporated into the extracellular matrix serve a primary structural function. Fibroblasts are one cellular source of fibronectin, a 440 kDa glycoprotein that is widely distributed within the extracellular matrix. Fibronectin facilitates cell adhesion to the matrix and cell migration through the matrix. Fibronectin has multiple functional domains which interact with proteins and proteoglycans of the extracellular matrix or with integrins on cell surfaces. Differential splicing of fibronectin RNA allows production of multiple isoforms of the protein that differ in the number and type of functional domains present. The complement of fibronectin isoforms that are synthesized changes during development and varies between different tissues. Laminin is an adhesive protein, produced by some fibroblasts, that is typically restricted to the basement membrane, where it interacts closely with type IV collagen. Laminin within the basement membrane provides a crucial substrate for attachment of epithelial cells.

Growth factors for fibroblasts

Multiple polypeptide growth factors stimulate the growth of fibroblasts. Most of these growth factors have mitogenic effects on several cell types, rather than being restricted in their action to fibroblasts. Platelet-derived growth factor (PDGF) is liberated from platelets that are activated following formation of a blood clot. It provides an initial stimulus for fibroblast proliferation following wounding and is also chemotactic for fibroblasts. The FGF family is a group of nine proteins with common structural fea-

tures. Of the FGFs, FGF-1 (acidic FGF) and FGF-2 (basic FGF) are the most widely expressed. FGF-1, FGF-2 and FGF-9 lack a typical signal sequence, suggesting that specialized mechanisms exist for the export of these proteins from cells. FGF-7, also known as keratinocyte growth factor (KGF), is a member of the FGF family with mitogenic effects that are restricted to epithelial cells. Epidermal growth factor (EGF) receptor ligands, including EGF and TGF α , also stimulate fibroblast growth.

Modulation of extracellular matrix production by fibroblasts

Fibroblasts regulate their secretion of extracellular matrix products in response to several types of signals. Proinflammatory cytokines are important positive and negative regulators of the production of collagen, elastin, proteoglycans and the metalloproteinases that are responsible for degradation and remodeling of the extracellular matrix. TGF β 1 and IL-1 are both strong activators of the transcription of collagen genes in fibroblasts. TGF β 1 also contributes to fibrogenesis by inhibiting metalloproteinase synthesis and stimulating the production of protease inhibitors that inhibit metalloproteinase activity. IL-4 stimulates the transcription of collagen and fibronectin in fibroblasts. In contrast, collagen production by fibroblasts is inhibited by other cytokines, including tumor necrosis factor α (TNF α) and interferon γ (IFN γ). Both TNF α and IL-1 enhance the synthesis of metalloproteinases by fibroblasts. Several human diseases characterized by chronic immune-mediated injury to a specific organ eventually progress to fibrosis of the affected organ; examples include scleroderma, idiopathic pulmonary fibrosis and chronic glomerulonephritis. In these diseases, combinations of proinflammatory cytokines that stimulate a net excess of extracellular matrix production by fibroblasts contribute to the development of pathologic fibrosis.

The composition of extracellular matrix produced by fibroblasts can also be influenced by environmental factors such as ultraviolet irradiation. A prominent abnormality in chronically photodamaged skin is solar elastosis, characterized by replacement of normal elastic and collagen fibers with abnormal elastic fibers. This ultraviolet light-induced pattern of injury results from the combination of chronic ultraviolet induction of matrix-degrading metalloproteinase enzymes and relative overproduction of elastin and fibrillins by dermal fibroblasts.

Cytokine production by fibroblasts

Most cytokine production by fibroblasts is not constitutive, but occurs following activation by agonists such as primary cytokines (i.e. IL-1 and TNF α), bacterial products (e.g. lipopolysaccharide) or T cell-derived cytokines (e.g. IL-17). Many of the cytokines that fibroblasts produce are also made by a wide variety of other cell types. These cytokines include IL-1 receptor antagonist (IL-1Ra), interleukin-6 (IL-6), interleukin-11 (IL-11), interleukin-15 (IL-15), GM-CSF, granulocyte colony-stimulating factor (G-CSF), macrophage colony-stimulating factor (M-CSF) and leukemia inhibitory factor (LIF). Fibroblasts can also be induced to make chemokines that are members of the α -chemokine family, of which IL-8 is the prototype, or the β -chemokine family, typified by monocyte chemoattractant protein 1 (MCP-1). Fibroblasts are a major paracrine source of KGF for epithelial cells such as epidermal keratinocytes. Other growth factors fibroblasts can be induced to synthesize are FGF-2 and hepatocyte growth factor (HGF). IL-1 and TNF α stimulation of fibroblasts also increases the activity of cyclo-oxygenase, leading to enhanced production of eicosanoids such as prostaglandin E₂. Even activated fibroblasts generally make only a subset of the cytokines listed in Table 1. The repertoire of cytokines elabor-

ated by fibroblasts at any given point in time is dependent on the combination of activating and inhibitory signals present in the local environment.

Fibroblasts and tissue repair

Fibroblasts play a central role in restoring the integrity of injured tissue. Soon after wounding, multiple molecules with chemotactic activity for fibroblasts are generated at the wound site. These include fragments of fibrin and fibronectin as well as several proteins released from platelet granules (PDGF, platelet factor 4 and β -thromboglobulin). Platelet factor 4 and β -thromboglobulin are both α -chemokines that are also chemotactic for neutrophils. Guided by their integrin receptors, fibroblasts migrate into the provisional wound matrix containing fibrin, fibronectin and vitronectin. The granulation tissue that forms in the first few days at a wound site contains numerous fibroblasts that are actively dividing under the influence of several fibroblast growth factors, including FGF-2, TGF α and PDGF. Fibroblasts in granulation tissue produce a rich collagenous matrix, including collagens I and III, that provides strength to the wound site. During the early stages of wound healing, fibroblasts produce more collagen III as a fraction of total collagen production than under normal resting conditions. Later on in the healing of a wound, some of this type III collagen is progressively replaced by type I collagen. Fibroblasts at wound sites have prominent cytoplasmic actin and myosin fibers and are sometimes referred to as myofibroblasts. The cytoskeletal bundles of actin and myosin in these myofibroblasts are associated with enhanced contractile function during the contraction phase of wound healing.

Concluding remarks

Fibroblasts either produce or respond to a substantial fraction of the mediators that participate in immune and inflammatory processes. The presence of fibroblasts and related connective tissue cells in nearly all organs and tissues ensures that these cell types have the opportunity to function as accessory cells influencing certain interactions between leukocyte populations. Fibroblast-generated extracellular matrix is also an important regulator of cell-cell interactions and signaling occurring via soluble mediators.

Table 1 Cytokines produced by stimulated fibroblasts

<i>Cytokine</i>	<i>Stimuli reported to elicit production</i>
TNF α	Ultraviolet B irradiation, lipopolysaccharide (LPS)
IL-1Ra	IL-1, TNF α
IL-6	IL-1, TNF α , IL-17
IL-11	IL-1, TGF β
IL-15	Ultraviolet B irradiation
C-X-C Chemokines ^a	
IL-8	IL-1, TNF α , IL-17
GCP-2	LPS
KC/Gro α	IL-1, TNF α , PDGF
C-C Chemokines ^a	
MCP-1	IL-1, TNF α , PDGF, LPS
RANTES	IL-1, TNF α
LIF	IL-1, TNF α
G-CSF	IL-1, TNF α , IL-17
M-CSF	IL-1
GM-CSF	IL-1
KGF (FGF-7)	IL-1, IL-6, TGF α , PDGF
FGF-2	IL-1
HGF	IL-1, TNF α

^aFibroblasts make multiple types of C-X-C (α) and C-C (β) chemokines. Not all of these molecules have been extensively studied, so this table lists only a few well-characterized members of the two major chemokine families that are known to be made by fibroblasts.

FIBRONECTIN

Fabrizio Mainiero and Angela Santoni, Department of Experimental Medicine and Pathology, University 'La Sapienza', Rome, Italy

Fibronectin (FN) is a ubiquitous extracellular glycoprotein endowed with many biological activities (Figure 1); it is present in a soluble form in plasma and in an insoluble form in the extracellular matrix (ECM). FN interacts with collagen, heparin, fibrin, and several cell surface receptors of the integrin family. These interactions play important roles in cell adhesion and migration, wound healing, hemostasis and thrombosis, inflammation and immune response, tumor invasion and embryonic differentiation.

Fibronectin structure and assembly

FN is a dimeric glycoprotein with a monomer molecular weight of 220–250 kDa composed almost entirely of three types of modules, known as types I (45 amino acids), II (60 amino acids) and III (90 amino acids). This glycoprotein is organized into proteolysis-resistant functional domains which contain binding sites for integrins, ECM and plasma

proteins (Figure 2). Interaction of FN with integrins is mainly mediated by the Arg-Gly-Asp (RGD) sequence that is incorporated in a stable protein scaffold provided by the tenth type III module. Additional residues (Pro-His-Ser-Arg-Asn) in the ninth type III module, known as the synergy region, are also involved in this interaction. In the same ninth type III module a binding site for $\alpha_{IIb}\beta_3$ -integrin is also present. Another major cell-adhesive domain is termed IIICS (type III connecting segment). This domain contains three important integrin-binding sites: Glu-Ile-Leu-Asp-Val-Pro-Ser (EILDVPS) in the CS1 region, Arg-Ala-Pro-Ser (REDV) in the CSS region, and Ile-Asp-Ala-Pro-Ser (IDAPS) in the adjacent heparin-binding domain (Figure 2).

FN matrices are deposited in a temporally and spatially defined pattern and comprise both newly synthesized cellular and soluble FNs. All five type I modules present in the N-terminal are required for FN assembly into the fibrillar matrix. The ninth type I domain in the collagen-binding region, and the first type III domain also appear to form a functional unit that is involved in FN assembly. This process is mediated by integrins including $\alpha_5\beta_1$ and $\alpha_v\beta_3$.

FN is encoded by a single gene whose pre-mRNA can be alternatively spliced in three different regions. Different isoforms of FN result from alternative splicing of EDA and EDB modules and mostly of a region termed V (variable) or IIICS. Multiple alternative splicing occurs in this region and generates 20 potentially different forms of FN.

Figure 1 Fibronectin is involved in many biological processes.

Figure 2 FN structure and domain organization. The modular structure of FN shows the position of the types 1, 2 and 3 modules. The positions of the alternatively spliced regions EDA, EDB and IIICS, which contain integrin-binding sites, are shown. The ninth type III module contains the synergy region. The tenth type III module contains the RGD sequence involved in integrin binding. The IDAPS sequence located near the carboxyl terminus of the heparin-binding domain of FN is involved in integrin binding. The other binding sites with the counterpart ligands are indicated by square brackets.

Fibronectin expression and distribution

FN is present in all body fluids and most abundantly in plasma (330–350 $\mu\text{g ml}^{-1}$). It is also widely distributed in the basement membranes and in the connective tissue matrices throughout the body, where it is expressed together with other ECM proteins. Cellular FN is mainly synthesized by fibroblasts and tissue macrophages. Chondrocytes, myoblasts, endothelial cells, astrocytes, Schwann cells, hepatocytes, kidney cells and keratinocytes also produce FN. Resting platelets, neutrophils and monocytes do not express surface FN, but they produce and release it upon activation during hemostasis and inflammation; T lymphocytes and natural killer (NK) cells constitutively synthesize and secrete FN.

Fibronectin ligands

FN interacts with a large number of molecules and ECM components including collagens, fibrin, fibrinogen, proteoglycans, and factor VIII via specific binding sites (Figure 2). FN specifically interacts with collagens (most strongly with collagen type III) and gelatin. FN binding to fibrin occurs on at least two different sites and plays an important role in the formation of blood clots and cryoprecipitates in the plasma. FN also interacts with and is a substrate for factor VIII. Factor VIII cross-links FN to fibrin during blood clotting and induces cross-linking of FN to collagen and bacteria. FN interaction with heparin

involves two specific sites in the C- and N-termini. FN interaction with gangliosides, phospholipids, C1q complement component, acetylcholinesterase and thrombospondin have been reported. Cell adhesion to FN is mostly mediated by cell surface receptors belonging to the integrin family. Integrins represent a large group of heterodimeric receptors that are of central importance in cell surface interactions between many cell types and a variety of ECM proteins including FN. Each integrin is composed of α and β subunits which are membrane glycoproteins with a large extracellular domain, a single membrane-spanning segment and a short cytoplasmic portion. Divalent cations regulate the association of α and β subunits and ligand binding. The extracellular portion of integrins binds to ligands, whereas the cytoplasmic domain interacts with cytoskeletal elements. A general model of the integrin structure is presented in Figure 3.

The RGD sequence specifically binds to $\alpha_5\beta_1$, $\alpha_3\beta_1$, $\alpha_v\beta_1$, $\alpha_v\beta_3$, $\alpha_{IIb}\beta_3$, $\alpha_v\beta_5$, and $\alpha_6\beta_6$. The $\alpha_{IIb}\beta_3$ -integrin can also interact with an 11 residue peptide present in the ninth type III module. The IIICS domain, with the adhesive sequences EILDVPS in the CS1 region and REDV in the CS5 region, and the adjacent heparin-binding domain, with the IDAPS sequence, provide the binding region for $\alpha_4\beta_1$ and $\alpha_4\beta_7$ integrins. The FN-binding integrins and FN recognition sequences are shown in Figure 4.

Figure 3 Integrin structure and domain organization. The N-terminal sequences of α and β subunits contribute to the ligand-binding site. The extracellular portion of the α subunit is characterized by the presence of a region which binds divalent cations. The I-domain is present only in some α subunits. The α subunits without an I-domain undergo intracellular proteolytic processing. The resulting heavy and light chains remain bound by a disulfide bridge. The β subunit is characterized by four cysteine-rich repeats and by an I-domain-like sequence.

Fibronectin and signaling

Engagement of FN receptors by FN or specific antibodies initiates biochemical signaling events within the cell important for regulating different cell functions such as migration, adhesion, proliferation, differentiation, apoptosis and specific gene expression. Recently, a variety of potential signaling mediators activated by FN interaction with integrins have been identified in many cell types: they include the focal protein tyrosine kinase FAK (pp125^{FAK}), the serine-threonine kinases PKC and MAPK, the adapter molecules SHC and GRB-2, the GTP-binding proteins p21 RAS and RHO, the phosphatidylinositol 3-kinase (PI3K). FN binding can also trigger other events, such as elevation of intracellular pH and Ca^{2+} transients. The FN signaling pathways are shown in Figure 5.

Fibronectin and development

Mutations of FN and FN-binding integrin genes in the mouse have provided exciting insights into their function during morphogenesis. Null mutations in either FN or the integrin α_5 gene lead to embryonic lethality. FN-null embryos develop abnormalities

shortly after gastrulation. Defects are found in mesodermal derivatives along the anterior-posterior axis and in the yolk sac vasculature. Mutant embryos lack notochord and somites along the entire axis, although precursors for these tissues are present.

Fibronectin, cell growth and apoptosis

Cellular interaction with FN promotes cell cycle progression and proliferation by affecting cyclins and immediate early response genes. Clustering of $\alpha_5\beta_1$ fibronectin receptor induces an increase in CDK-2 and CDC-2-dependent kinase activity accompanied by hyperphosphorylation of the retinoblastoma protein, Rb. In addition, cell adhesion to FN results in a rapid induction of *c-fos* and *c-myc* transcripts. FN is also involved in cell survival and protection from apoptosis in many cell types, including epithelial and endothelial cells and leukocytes. In human endothelial cells FN or FN-binding integrins, which trigger the RAS-MAPK pathway via SHC, arrest apoptotic cell death even in absence of mitogens; in Chinese hamster ovary (CHO) cells increased expression of Bcl-2 gene, which is a potent antagonist of apoptosis, is specifically induced by $\alpha_5\beta_1$ ligation; adhesion to FN via $\alpha_4\beta_1$ prolongs cosinophil

Figure 4 Integrin-binding sites and recognition sequences on FN. The RGD sequence in the tenth type III module mediates binding to the indicated integrins. The PHSRN sequence, in the ninth type III module, mediates binding to the $\alpha_{11b}\beta_3$ integrin. The LDV and REDV sequences in the alternatively spliced IIICS bind $\alpha_4\beta_1$ and $\alpha_4\beta_7$ -integrins. The IDAPS sequence located near the carboxyl terminus of the heparin-binding domain of FN is also recognized by the $\alpha_4\beta_1$ integrin.

Figure 5 FN signaling pathways. The major intracellular signaling pathways activated by FN via integrin ligation are indicated.

survival by triggering production of cytokines. In some cases, however, leukocytes can respond to FN by undergoing apoptosis rather than proliferating or surviving. Growth of myeloid leukemia and several hematopoietic cells is suppressed by seeding on FN which triggers apoptosis by interaction with $\alpha_5\beta_1$.

Fibronectin and the immune system

Many studies indicate that FN plays an important role in the regulation of lymphocyte activation, differentiation and function. Induction of thymocyte differentiation depends on FN interaction with both $\alpha_4\beta_1$ and $\alpha_5\beta_1$ -integrins. Enhancement of T cell receptor (TCR)-mediated T cell activation occurs following either ligand-induced or antibody-mediated cross-linking of $\alpha_4\beta_1$ and $\alpha_5\beta_1$ -integrins. FN costimulates CD4⁺ T cell proliferation, expression of activation markers, including CD25 and CD71, and interleukin 2 (IL-2) production. Interestingly, regulation of IL-2 gene expression is related to the ability of FN to induce the expression of AP-1 transcription factor. FN also potentiates the cytotoxic activity of CD8⁺ T lymphocytes and NK cells. In cytotoxic T cells, the costimulatory activity has been associated with the enhancement of TCR-induced inositol

1,4,5-triphosphate (IP₃) generation whereas in NK cells it is associated with the potentiation of CD16-triggered calcium flux. In B cells, FN interaction with $\alpha_4\beta_1$ affects the maturation of bone marrow cells into immunoglobulin-secreting cells.

Fibronectin, inflammation and phagocytosis

During inflammation, leukocytes extravasate into the tissue stroma where they produce a variety of cytokines that trigger the inflammatory response. It is well established that FN induces the expression of several cytokine genes, including IL-1 β and CSF-1 in monocytes, and of specific protease genes in synovial fibroblasts. Numerous studies have reported that phagocytes and microorganisms such as staphylococci, streptococci, gram-negative bacteria and *Candida albicans* interact with FN and that FN promotes phagocytosis of various particles and microorganisms. FN does not act as a classical opsonin (i.e. IgG1, C3b) but rather functions as an enhancer of phagocytosis mediated by other receptors on phagocytic cells. Indeed, C3b receptors and Fc receptors appear to be activated for phagocytosis by occupation of FN receptors by FN on the same cell. In addition, FN acts as a costimulus with cytokines for induction of the respiratory burst in neutrophils.

FN may play an important role for activation of phagocytes in extravascular locations such as wound beds and interstitial spaces where they are attached to the ECM.

Fibronectin and hemostasis

FN participates in the interaction of platelets with the fibrin matrix during clot retraction and in physiologically important processes including clot dissolution, clearance of fibrin debris, and clot formation on wound healing. Platelets contain an intracellular pool of FN, which is located in α granules and is released upon activation with thrombin or collagen. The $\alpha IIb\beta_3$ -integrin which binds to both cell-associated and released FN is expressed on the platelet cell surface. FN plays a relevant role in the primary response of hemostasis by mediating platelet adhesion and spreading on subendothelial basement membranes, and in platelet-platelet interaction cooperating with fibrinogen and thrombospondin. FN also interacts with fibrin, is incorporated into clots and is cross-linked to the fibrin by factor VIII.

Fibronectin, wound healing and fibrosis

The healing of epidermal wounds is a good model to analyze the role of FN. When a wound is made in the skin, the first detectable event is the formation of a fibrin-FN clot which promotes the migration of epidermal cells to cover the wound. Moreover, FN synthesis in the underlying and surrounding dermis and FN-binding integrins on the keratinocytes become activated. Meanwhile, in the granulation tissue which contains fibroblasts and phagocytes, FN, produced also by the immigrating cells, promotes fibroblast migration and fibrillogenesis of collagen type I. The FN role in the neovascularization process is less clear, but several studies suggest its involvement in migration and proliferation of endothelial cells. Furthermore, FN is a chemotactic factor for many cells and it is produced by activated neutrophils and macrophages. The possibility arises that cells recruited and activated in response to FN produce more FN, thus leading to ECM accumulation and fibrosis.

Fibronectin and cancer

Tumor cells often show cell type-specific changes in FN receptor expression and function, associated either with malignant transformation or with tumor progression and metastasis. A loss of $\alpha_5\beta_1$ expression has been found in several human and experimental tumors and an inverse relationship between malignant behavior and $\alpha_5\beta_1$ levels has been described for some tumor cell lines. In addition, overexpression of $\alpha_5\beta_1$ -integrin in CHO cells results in reduced migration *in vitro* and loss of tumorigenicity *in vivo* of transfected cells as compared with parental cells expressing low levels of FN receptors. $\alpha_5\beta_1$ /FN matrix interactions are also implicated in the control of metastasis as coinjection of tumor cells with RGD-containing peptide or antibodies to $\alpha_5\beta_1$ results in inhibition of experimental tumor spreading.

FILARIASIS, LYMPHATIC

Thomas B Nutman, Laboratory of Parasitic Diseases, NIAID, National Institutes of Health, Bethesda, Maryland, USA

Lymphatic filariasis is caused by thread-like nematodes of three filarial species, *Wuchereria bancrofti*, *Brugia malayi* and *Brugia timori*. While *W. bancrofti* is responsible for infections in more than 90% of the

estimated 90 million individuals infected, *B. malayi* accounts for all but 40 000–50 000 of the infections in the remaining 10 million. Infection is established only after a mosquito vector transmits infective

larvae during a blood meal. These infective larvae molt twice and mature over a period of 6 months to 2 years, finally becoming mature adults that reside within the host's lymphatic vessels. The adult females continuously produce microfilariae that circulate in the blood, often with a periodicity that is nocturnal. These microfilariae cannot develop further until they are ingested by a mosquito. In the mosquito, they complete their life cycle by developing over a 2 week period into mature third stage (L3) larvae, again capable of being infectious for humans. The parasites are long lived. The average lifespan of an adult is estimated to range from 5 to 15 years, while microfilariae have a lifespan of 3–12 months. Because of their long period of survival and their inability to replicate in the definitive (human) host, these parasites have developed complex and specialised mechanisms to evade killing by the host immune effector mechanisms.

Clinical manifestations in all three lymphotic filariases are quite similar but also wide ranging. Although the most characteristic are those reflecting the consequences of lymphatic dysfunction, damage or inflammation (e.g. elephantiasis, hydrocele, retrograde adenolymphangitis), the most common manifestation is an asymptomatic state characterized by high levels of circulating microfilariae associated with a relatively downregulated cellular immune response. A much rarer condition, tropical pulmonary eosinophilia, appears to be a result of specific immunological hypersensitivity to the parasite, characterized by pulmonary interstitial inflammation with marked peripheral blood eosinophilia and extraordinary elevations of serum immunoglobulin E (IgE). Further, there are individuals clearly exposed to the parasite but who have no obvious signs of infection. This 'endemic normal' group is likely to be a heterogeneous one ranging from those harboring cryptic or occult infections to those who may be solidly immune.

Better definition of the parasitologic status of all individuals (infected and uninfected) living in filarial-endemic regions has been made by the use of specific tests for circulating parasite antigen (for *W. bancrofti*), IgG4 filarial-specific antibodies (for both bancroftian and brugian filarial infection) – felt to reflect active infection – and the use of high resolution ultrasonography to detect the living adult worms *in situ* (generally in the scrotal lymphatics of males).

Immunological features

In response to filarial infection, high levels of parasite-specific antibodies are produced, although the

distribution of immunoglobulin isotypes varies considerably depending on the clinical expression of infection. Asymptomatic microfilaremic individuals have high levels of filarial-specific IgG4, whereas those with chronic lymphatic obstruction have predominantly IgG1, IgG2 and IgG3. Antifilarial IgE levels are elevated in most infected groups, with the highest levels in those with tropical pulmonary eosinophilia. As the IgE and IgG4 antibodies are often directed at the same antigenic determinants and are regulated by similar cytokines (interleukins IL-4 and IL-13), the balance between IgG4 and IgE within a given individual has been postulated as being important in preventing allergic manifestations in these infections or in mediating parasite clearance and/or pathology.

Lymphocytes from individuals with asymptomatic microfilaremia generally display little or no proliferative response to parasite antigen, responses that contrast significantly to those seen in microfilarial-negative individuals with chronic lymphatic disease and those termed endemic normals. This lack of T cell reactivity in microfilaremic individuals has been shown to be parasite antigen-specific, in that proliferative responses to nonparasite antigens and mitogens remain intact. Analyses of parasite antigen-driven cytokine responses (based on mRNA levels, protein expression and cytokine-producing T cell frequencies) have shown that the asymptomatic microfilaremic individuals have a relative inability to produce interferon γ (IFN γ) while retaining the capacity to produce IL-4 and IL-5; those with chronic lymphatic pathology (particularly those who are negative for circulating parasite antigen) make IFN γ , IL-4 and IL-5 in response to the parasite antigen.

IL-10 appears to play a significant role in modulating the production of IFN γ in the microfilaremic state, as neutralizing IL-10 antibodies enhance both lymphocyte proliferation and IFN γ production in peripheral blood mononuclear cells from asymptomatic microfilaremic individuals, and IL-10 production, both spontaneously *ex vivo* and in response to parasite antigen, is markedly enhanced in cells from microfilaremic individuals.

In animal models of filarial infection (where time of infection can be ascertained), parasite-specific unresponsiveness develops at the time microfilariae appear in the bloodstream, suggesting that this stage of the parasite is involved in the modulation of the cellular immune system. Further, in *in vitro* studies using human cells stimulated with stage-specific antigen preparations, stages containing microfilariae (Mf and adult females) have been shown to preferentially

downregulate the cellular (IFN γ , proliferation) responses.

A number of mechanisms apart from the down-regulation of the immune response by immunoregulatory cytokines (e.g. IL-10) have been proposed for the diminished or absent proliferative and IFN γ response toward parasite antigens seen in the asymptomatic microfilaremic individual. Although there is some evidence for a role of host genetic factors (particularly certain HLA class I and class II alleles) in determining the nature of the immune response to parasite antigens, studies in endemic populations have shown that prenatal exposure to the microfilarial stage antigens occurs in filarial-endemic regions and can result in long-term 'anergy' to filarial antigens once naturally infected.

Determinants of pathology

While the nature (quality, quantity) of the immune response has been proposed as a major determinant of disease in lymphatic filariasis, based on differences in measurable immune responses among infected but clinically distinct populations, the parasite itself (or parasite-derived products) has also been implicated as another important determinant of pathology. Indeed, in various immunodeficient strains of mice (athymic nude, SCID) severe lymphatic dilatation occurs in the absence of a mature T and B cell response. Interestingly, with immune reconstitution of these filarial-infected immunodeficient mice, the lymphatics become markedly obstructed, suggesting that there are two pathologic phases in lymphatic filariasis – one parasite-mediated and the other immunologically-mediated. Further, there is evidence that much of the severely deforming manifestations of lymphatic filariasis may be caused by bacterial and fungal infections superimposed on poorly functioning lymphatics.

Protective immunity

There is evidence for protective immunity to filarial

parasite. Foremost is the observation in filariasis that the adult worm burden generally increases through childhood and adolescence, but then plateaus or falls in adulthood. This observation can be explained by the acquisition of so-called concomitant immunity where an individual develops resistance to new infection while harboring adult parasites.

In filarial infection, a small group of individuals appear to be infection free despite long-term residence in areas of high endemicity, the so-called 'putative immune' (PI) or 'endemic normal' group. However, such individuals with sterile immunity are not commonly identified.

Models of filarial infections in susceptible animals (e.g. jirds infected with *B. malayi*) provide the most compelling evidence that protective immunity can be induced by attenuated larvae or by repeated infections. Indeed, partial protection has been induced with defined antigens such as paramyosin. Nevertheless, the effector mechanisms underlying this immunity have not been determined nor have universal targets of immune attack. Thus, vaccine development for lymphatic filarial infections is in its infancy.

FILOVIRUSES (MARBURG VIRUS AND EBOLA VIRUS), INFECTION AND IMMUNITY

Hans-Dieter Klenk and Heinz Feldmann, Institut für Virologie,
Philipps-Universität Marburg, Marburg, Germany

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Filoviruses cause fulminating hemorrhagic fever with severe shock syndrome and high mortality in humans and nonhuman primates. Marburg virus, the prototype of these agents, was discovered during an outbreak in Europe in 1967. Ebola virus was first isolated in 1976 as the causative agent of two simultaneous outbreaks in southern Sudan and northern Zaire. Re-emergence, particularly of Ebola virus, has since been observed, with irregular intervals. Filovirus infections are of zoonotic nature, although the natural reservoir is not known. The epidemiological characteristics of identified outbreaks are summarized in Table 1.

Characteristics of the organism and its antigens

Filoviruses are a family of nonsegmented negative-stranded RNA viruses, with Marburg virus and Ebola virus constituting two different species. Particles are filamentous with a variable length (up to 14 000 nm) and a uniform diameter (80 nm) (Figure 1).

Inside an envelope there is a nucleocapsid containing the RNA genome (19 kb) and four internal proteins. These are the L-protein catalyzing transcription and replication, the phosphoprotein VP35 that

Table 1 Outbreaks of filoviral hemorrhagic fevers

Location	Year	Virus/subtype	Cases (% mortality)	Epidemiology
Germany/Yugoslavia	1967	Marburg	32 (23)	Imported monkeys from Uganda source of most human infections
Zimbabwe	1975	Marburg	3 (33)	Unknown origin; index case infected in Zimbabwe; secondary cases were infected in South Africa
Southern Sudan	1976	Ebola/Sudan	284 (53)	Unknown origin; spread mainly by close contact; nosocomial transmission and infection of medical staff
Northern Zaire	1976	Ebola/Zaire	318 (88)	Unknown origin; spread by close contact and by use of contaminated needles and syringes in hospitals
Tandala, Zaire	1977	Ebola/Zaire	1 (100)	Unknown origin; single case in missionary hospital; other cases may have occurred nearby
Southern Sudan	1979	Ebola/Sudan	34 (65)	Unknown origin; recurrent outbreak at the same site as the 1976 outbreak
Kenya	1980	Marburg	2 (50)	Unknown origin; index case infected in western Kenya died, but physician secondarily infected survived
Kenya	1987	Marburg	1 (100)	Unknown origin; expatriate traveling in western Kenya
USA	1989–90	Ebola/Reston	4 (0)	Introduction of virus with imported monkeys from the Philippines; four humans asymptotically infected
Italy	1992	Ebola/Reston	0 (0)	Introduction of virus with imported monkeys from the Philippines; no human infections associated
Ivory Coast	1994	Ebola/Ivory Coast	1 (0)	Contact with chimpanzees; single case
Gabon	1994	Ebola/Zaire	Unknown	Unknown
Kikwit, Zaire	1995	Ebola/Zaire	315 (77)	Unknown origin; course of outbreak as in 1976
Gabon	1996	Ebola/Zaire	50 (50)	Outbreak was linked to the butchering, transport and preparation for consumption of a dead chimpanzee
USA	1996	Ebola/Reston	0 (0)	Introduction of virus with imported monkeys from the Philippines; no human infections associated
Gabon	1996–97	Ebola/Zaire	60 (75)	Uncommon origin: index case was a hunter

Figure 1 Characteristics of filoviral particles. (A) Electron micrograph. Budding of Marburg virus particles from the plasma membrane of infected primary cultures of human endothelial cells. Particles consist of a nucleocapsid surrounded by a membrane in which spikes are inserted (arrows). The nucleocapsid contains a central channel (inset). The plasma membrane of infected cells is often thickened at locations where budding occurs (arrowheads). Ultrathin section – bar 0.5 μm ; bar inset, 50 nm. (B) Four proteins are involved in the nucleocapsid formation; polymerase or large (L) protein (ellipse), nucleoprotein (NP) ($\bullet$), virion structural protein (VP) 30 ($\square$) and VP35 (Δ). The glycoprotein (GP) is a transmembrane protein and anchored with the carboxy-terminal part in the virion membrane. Homotrimers of GP form the spikes on the virion surface (arrows in (A)). VP40 and VP24 are membrane-associated proteins. (C) Genome organization of filoviruses. Filoviral genomes consist of a single, negative-stranded, linear RNA molecule. Differences in organization between viruses of the Marburg and Ebola species are indicated. *, Position of gene overlap; Ebola, isolate Mayinga, subtype Zaire; G, glycoprotein gene; L, polymerase (L) gene; Marburg, isolate Musoke; N, nucleoprotein gene; 24/30/35/40, virion structural protein (VP) genes.

may function as a cofactor to the L-protein, the major nucleoprotein NP encapsidating the genome, and VP30 that may be a second nucleoprotein. The envelope consists of a lipid membrane derived from the plasma membrane of the host cell and a transmembrane glycoprotein GP which forms the spikes at the surface of the virion. There are two additional

membrane-associated proteins, the matrix proteins VP40 and VP24 of unknown function. Replication and transcription of predominantly monocistronic mRNA occur in the cytoplasm, as is the case with most nonsegmented negative-stranded RNA viruses. Full length GP of Ebola virus is expressed from two open reading frames by a mechanism of transcrip-

tional editing. A nonedited transcript of the GP gene yields a small soluble glycoprotein. Synthesis of Marburg virus GP does not require such an editing mechanism.

Clinical syndrome and pathogenesis

Transmission by intimate contact with skin and secretions of infected patients is the main route of filovirus infection for humans. After 4–16 days of incubation there is an abrupt onset of disease with fever, headache, anorexia and myalgia, followed by nausea, vomiting, sore throat, abdominal pain and diarrhea. At their first clinical examination, patients usually show already signs of severe illness with dehydration, apathy and desorientation, and may develop a characteristic nonpruritic, maculopapular centripetal rash. Hemorrhagic manifestations develop during the peak of the illness. Bleeding into the gastrointestinal tract is most prominent, along with petechiae and hemorrhages from puncture wounds and mucous membranes. Death occurs between days 7 and 16 after onset of disease and is usually associated with severe hemorrhages and hypovolemic shock. Mortality ranges between 20% (Marburg) and almost 90% (Ebola-Zaire). With Ebola-Reston, there is no evidence for human pathogenicity.

Pathophysiological changes that make filovirus infections so devastating are just beginning to be unraveled. Clinical and biochemical findings support the anatomical observations of extensive liver involvement, renal damage, changes in vascular permeability, including endothelial damage, and activation of the clotting cascade. The visceral organ necrosis is a consequence of virus replication in parenchymal cells. However, no organ, not even liver, shows sufficient damage to account for death. The role of disseminated intravascular coagulation (DIC) in pathogenesis is still controversial, as a laboratory confirmation of DIC in human infections has never been demonstrated.

Laboratory parameters in the crucial early stage of filovirus hemorrhagic fever (HF), such as high AST/ALT (aspartate aminotransferase/alanine aminotransferase) ratio, normal bilirubin levels, and marked lymphopenia followed by a dramatic neutrophilia with left shift, suggest extrahepatic targets in the infection. As with some other HFs (hemorrhagic fever with renal syndrome (HFRS), dengue HF, Lassa fever), fluid distribution problems and platelet abnormalities are dominant clinical manifestations indicating dysfunction or damage of endothelial cells and platelets. At postmortem examination there is little monocyte/macrophage infiltration in sites of

parenchymal necrosis, suggesting that a dysfunction of white blood cells, such as macrophages, also occurs. Morphological studies on Ebola-Reston infected monkeys from the 1989 epizootic and monkeys experimentally infected with Ebola-Zaire showed that monocytes/macrophages and fibroblasts may be the preferred sites of virus replication in early stages, whereas other cell types may become involved as the disease progresses. Human monocyte/macrophages in culture are also sensitive to infection, resulting in massive production of infectious virus and cell lysis. Although, the studies on infected non-human primates did not identify endothelial cells as sites of massive virus replication, *in vitro* studies and autopsy observations of human cases clearly demonstrated that endothelial cells of human origin are suitable targets for virus replication. Here, infection leads to cell lysis, indicating that damage to endothelial cells may be an important pathophysiological parameter during infection.

Besides evidence for direct vascular involvement in infected hosts, the role of active mediator molecules in the pathogenesis of the disorders needs to be discussed. Although the source of these mediators during filovirus infections is still unknown, candidate cells exist. In addition to the endothelium, which has yet to be examined for production and secretion of such mediators, the common denominator remains the monocyte/macrophage, a cell type shown to be a major site of virus replication *in vivo* and *in vitro*. Monocytes/macrophages are known as a pivotal source of different proteases, H_2O_2 , and mediators such as tumor necrosis factor α (TNF α), interleukin 6 and 8, and platelet-derived growth factor (PDGF). TNF α can result in secondary activation of mediators with important protective as well as deleterious effects. Recently it has been demonstrated that supernatants of filovirus-infected monocyte/macrophage cultures are capable of increasing para-endothelial permeability in an *in vitro* model. Examination for mediators in those supernatants revealed increased levels of secreted TNF α . These data support the concept of a mediator-induced vascular instability, and thus increased permeability, as a key mechanism for the development of shock syndrome seen in severe and fatal cases. Thus the syndrome may be comparable to shock symptomatic in response to various endogenous and exogenous mediators. The bleeding tendency could be due to endothelial damage caused directly by virus replication as well as indirectly by cytokine-mediated processes. The onset of the bleeding tendency is supported by the loss of the integrity of the endothelium, as demonstrated in tissue and organ culture and infected animals. The hemorrhage occurs later in

infection and could be due to extended damage which cannot be repaired by wound-healing mechanisms. The combination of viral replication in endothelial cells and virus-induced cytokine release from monocytes/macrophages may also promote a distinct proinflammatory endothelial phenotype that then triggers the coagulation cascade. A model of these pathophysiological events is shown in Figure 2.

Immune responses of the host

Fatal filovirus infections usually end with high viremia and no evidence of an effective immune response. In monkeys infected with Ebola–Reston virus nonprotective antibodies have been observed shortly before death. Altogether, however, the data available to date do not support an important role of neutralizing antibodies in virus clearance. Since circulating monocytes/macrophages are primary target cells in filovirus infections, and since the extensive disruption of the parafollicular regions in spleen and lymph nodes results in the destruction of the antigen-presenting dendritic cells, cellular immunity appears also to be affected during filoviral HF. In addition to these cytolytic effects, there are several other mechanisms by which filoviruses may interfere with the immune system. Firstly, the high carbohydrate content of Marburg and Ebola virus GP may suppress its immune reactivity. Secondly, the non-structural glycoprotein that is secreted from cells infected with Ebola virus may interfere with the

virus-directed immune response. Thirdly, a fragment of spike GP which is also secreted in large amounts from infected cells may have similar effects. Fourthly, filovirus GP displays a sequence motif homologous to an immunosuppressive domain observed in retroviral glycoproteins. Altogether, there is now a large body of evidence indicating that filoviruses induce immunosuppression in the infected host, which appears to be a major factor for the rapid generalization and the severity of the disease.

Vaccines

Although neutralizing antibody titers in human convalescent sera can barely, if at all, be detected in laboratory tests, there are anecdotal case reports suggesting the potential benefit of passive immunization against Ebola virus infection. Furthermore, recent reports from the 1995 outbreak in Zaire, about effective treatment of acutely ill patients with whole blood transfusions from convalescent donors, suggest that quantities of antibodies, predicted to be marginally effective in laboratory tests, may still be protective. A study in which Ebola virus-infected monkeys have been treated with equine hyperimmune serum indicated that passively acquired antibody can also have a beneficial effect in reducing the viral burden. Effective treatment of human patients, however, may require antibodies with higher specific activities and more favorable pharmacokinetic

Figure 2 Possible role of macrophages and endothelial cells in the development of hemorrhagic fever caused by filoviruses. EC, endothelial cell; MAC, macrophage; Vir, virus particle; CAM, cell adhesion molecule; E, erythrocyte; BM, basement membrane; N, nucleus; V, vacuole.

properties than the presently available equine immunoglobulin.

There is experimental evidence that active immunization employing killed virus and recombinant Ebola and Marburg virus glycoproteins is partially successful in animals, suggesting that this may be a feasible strategy for eliciting protective immunity. At present, however, vaccines for human application are not available. It should also be mentioned in this context that filoviruses are relatively resistant to the *in vitro* antiviral action of interferon, and prophylactic interferon administration to monkeys has failed to increase survival or reduce virus titers, although a slight prolongation of time to death was observed. Finally, no antiviral drugs are available for filovirus treatment either.

FISH IMMUNE SYSTEM

A E Ellis, SOAEFD Marine Laboratory, Aberdeen, UK

It is important to realize that among the Vertebrata, the class Pisces has within it the oldest and most numerous species. The most recent and evolutionarily advanced group of fish, and the one of most commercial importance, is the teleosts (bony fish), which first appeared in the late Devonian Age, 300 million years ago, and rose to prominence 70 million years ago. Now they are the most numerous with over 20 000 extant species (compared with the 4500 species of mammals) occupying very diverse aquatic habitats. It is to be expected, therefore, that interspecies differences will exist in the immune system of fish. Most of the available information appertains to the teleosts, and in particular to a few species of commercial importance in aquaculture. Differences among these species are not considerable and this entry presents a generalized picture of the teleosts only, there being no attempt to draw attention to anatomical, cellular or molecular differences which exist between teleosts and other groups of fish for which data exist, e.g. the hagfish and lamprey (Agnatha) or the sharks and rays (Chondrichthyes).

Functional anatomy of the fish immune system

The primary and secondary lymphoid tissues of fish

are located in the thymus, kidney and spleen (**Figure 1**). Of course, the whole integument of fish, including the skin, is a mucous membrane and contains immune cells and secretions. The gills are important in antigen uptake (see Vaccination of Fish below). Fish do not possess lymph nodes or organized gut-associated lymphoid tissues, although the gut and gill do contain lymphoid and antibody secreting cells.

The *thymus* is a paired organ located dorsolaterally in the gill chamber. In ontogeny it is the first organ to become lymphoid and arises within the epithelium, external to the basement membrane, between the gill arches. In young fish it is covered externally only by a single layer of epithelial cells. With age, the thymus becomes surrounded by a thin connective tissue capsule which gradually invades the lymphoid tissue in a slow process of involution. In most species the thymus retains a very superficial position.

In structure and function the fish thymus is similar to that of mammals except in some details. It is composed mainly of lymphocytes in various stages of development and division and a few epithelial-type cells and macrophages are also present. However, differentiation into cortex and medulla and presence of Hassell's corpuscles are not marked. Blood vessels within the organ possess a specialized endothelium

Figure 1 Lymphoid organs of teleost fish. (A) The thymus insert is that of Atlantic salmon eight days pre-hatch. The thymocytes develop within the pharyngeal epithelium, external to the basement membrane (bm). The organ is covered externally by a single layer of squamous epithelium. gb, primary gill bars. (B) The kidney insert is that of the plaice, a flatfish, showing the melanomacrophage centers and kidney tubules surrounded by hematopoietic tissue. (C) The spleen depicts the branching ellipsoid system within the splenic pulp.

with tight junctions. There is considerable evidence to indicate that the fish thymus, as in higher vertebrates, is a primary lymphoid organ. Such evidence includes the exclusion of foreign particles and anti-

gens present in the circulation, the exclusion of circulating lymphocytes, the high mitotic rate of thymocytes, which is presumably antigen independent, the absence of antibody-producing cells, the migration

of thymocytes to other lymphoid organs and the fact that the relative size of the organ is greatest in young fish. Data appertaining to lymphocyte subpopulations indicate that the thymocytes of fish are similar in many respects to the T cell lineage in mammals (see below). Unfortunately the crucial experiments of early thymectomy to show ablation of T cell function have proved difficult to perform in fish as the organ contains lymphocytes at or soon after hatching.

The *kidney* is the major hematopoietic and immunologically reactive organ in teleost fish. The organ is located ventral to the spinal chord and extends the full length of the peritoneal cavity. The anterior tip (so-called 'head kidney' or pronephros) is constituted entirely of hematopoietic and lymphoreticular tissues, which, in the rest of the organ (opisthonephros), occupy the intertubular spaces. The hematopoietic tissue bears close resemblance to the bone marrow of higher vertebrates but differs in having a highly active reticuloendothelial system and is the major antibody-producing tissue of fish. In this respect it has functional similarity to mammalian lymph nodes. However, there is no anatomical differentiation of the lymphoid tissue and no primary or secondary lymphoid follicles in fish. Within the hematopoietic tissue are many pigment-containing cells, termed melanomacrophages. These macrophages contain melanosomes and to a greater or lesser degree ceroid and lipofuscin.

In primitive teleosts (e.g. salmonids) the pigment cells are scattered throughout the tissue, while in advanced species (e.g. flatfish and cyprinids) they form aggregates, termed melanomacrophage centers, which possess a delicate reticulin fiber capsule and contain other cell types, particularly lymphocytes and pyroninophilic cells. Foreign materials (e.g. carbon particles) in the circulation are actively phagocytosed by cells of the reticuloendothelial system lining the hematopoietic sinuses. These phagocytes then migrate and aggregate within melanomacrophage centers.

The *spleen* of fish is mainly composed of red pulp sinuses, while the white pulp is poorly differentiated, forming a cuff of tissue surrounding melanomacrophage centers, similar to those in the kidney and the extensive ellipsoid system. The latter comprises the whole of the splenic arterial capillary network, the vessels of which are surrounded by a thick sheath of reticulin fibres, embedded in which are numerous macrophages which phagocytose foreign particulate matter in the blood and, like the reticuloendothelial cells of the kidney, then migrate and accumulate in the melanomacrophage centers. Following antigen stimulation, antibody-producing cells

appear in the spleen but are less numerous than in the kidney tissue.

The origin and function of melanomacrophage centers in fish kidney and spleen is far from clear but the available information suggests they may be primitive analogs of germinal centers in higher vertebrates. Following antigen stimulation, clusters of pyroninophilic cells appear in the kidney hematopoietic tissue and the splenic ellipsoid walls and it is thought these clusters develop into melanomacrophage centers. The latter are also focal points for the aggregation of replete macrophages, and studies on lymphocyte recirculation in fish have demonstrated that small lymphocytes also migrate to the centers. Furthermore, immune complexes are trapped by reticulin fibers in the spleen and kidney, especially within the splenic ellipsoids and melanomacrophage centers, where they are retained for several months. The function of germinal centers in mammals is concerned with immunologic memory and the finding that priming fish with immune complexes, besides resulting in immediate trapping within ellipsoids and melanomacrophage centers, also induces stronger immunologic memory than priming with antigen alone, suggests that the ellipsoid and melanomacrophage system of fish serves a similar function.

The role of melanin associated with phagocytes in fish is not clear but a possible explanation is that as fish tissue lipids are highly unsaturated they are particularly susceptible to oxidation by free radical reactions initiated by phagocytic cells. The melanosomes present in highly phagocytic tissues in fish may function to quench the free radical chain reactions and protect the cells from severe damage.

Lymphocyte subpopulations in fish

While convincing evidence now exists for lymphocyte heterogeneity in fish, the extent to which functional diversity among lymphocyte populations have evolved in fish is still not clear. What can be said is that a T and B lymphocyte dichotomy basically similar to that of higher vertebrates has evolved in fish. The evidence supporting this view rests upon studies of surface markers, mitogen and carrier-hapten responses, and cytokine production.

The presence of surface immunoglobulin (sIg) molecules, detected by labelled antisera to serum Ig, is a characteristic of mammalian B lymphocytes. In fish, such techniques stain all lymphocytes, including thymocytes. However, studies using monoclonal instead of polyclonal antibodies specific to serum Ig stain only about 30% of peripheral lymphocytes and do not stain thymocytes. The polyclonal antibody staining of fish thymocytes is thought to be due to carbo-

hydrate moieties on thymocyte membranes and serum Ig which cross-react. In combination with other data (see below), it seems likely that the fish B-like lymphocyte antigen receptor is sIg, as in higher vertebrates. The fish T-like lymphocyte antigen receptor is still uncharacterized but recent genetic studies have indicated that gene fragments coding for molecules homologous to mammalian T cell receptor β chains occur in the goldfish and salmonids and strongly suggest that the nature of the T cell receptor in fish is basically similar to that in all other vertebrates.

The use of monoclonal antibodies in conjunction with mitogen or carrier-hapten responses provide compelling evidence for the presence of T and B lymphocyte types in fish. Examples of such evidence include the correlation between the presence of sIg and responsiveness to lipopolysaccharides (LPS; a B cell mitogen) and the lack of sIg with responsiveness to concanavalin A (Con A, a T cell mitogen). A monoclonal antibody has been produced which reacts with channel catfish sIg⁻ but not sIg⁺ blood lymphocytes. The proportions of these cell types in the blood were 46 and 38% respectively. This monoclonal stained virtually all thymocytes. The population of peripheral blood lymphocytes reacting with this monoclonal antibody was also shown to respond to con A stimulation as well as act as T helper cells but not antibody-producing cells in *in vitro* primary hapten-specific antibody responses. Thus, this monoclonal antibody appears to react with cells possessing typical T lymphocyte functions. Conversely, the population of peripheral lymphocytes not reacting with this monoclonal but reacting positively with a monoclonal to serum Ig were capable, after separation by panning, of *in vitro* antibody production to the T-independent antigen TNP-LPS, but not to the T-dependent antigen TNP-KLH. Responsiveness to the latter was restored by the sIg⁺ population. The nature of the marker on sIg⁻ cells reacting with the above monoclonal has not been characterized but molecular weight studies and the fact that it also cross-reacts with certain brain cells suggests it may be similar to mammalian Thy-2.

Studies on separated sIg⁺ and sIg⁻ blood lymphocytes in trout have shown the latter, but not the former, to be capable of producing a factor with macrophage-activating and interferon activity.

Thus, with the use of monoclonal antibodies fish lymphocytes may be separated into distinct subpopulations with functions homologous to mammalian T and B cells.

Concerning the origin of T and B lymphocytes in fish, as virtually all thymocytes possess characteristics of T lymphocytes and none of B lymphocytes,

it seems likely that the thymus in fish is the principal source of T lymphocytes, as in higher vertebrates. Analysis of other lymphoid organs (i.e. kidney and spleen) show there to be a mixed population of T and B cells but both organs possess large quantities of blood which contains both T and B cells. However, as the only organ containing significant amounts of lymphopoietic tissue in teleost fish is the kidney hematopoietic tissue, and this is also the most important source of antibody-producing cells, it must be more than likely that the kidney is the source of B lymphocytes.

Other leukocytes and related cell types

Monocytes and *macrophages* are morphologically and cytochemically similar to their mammalian counterparts. Macrophages are widespread in tissues, including the gills, where they are thought to play an important role in vaccine uptake (see below); they form an extensive reticuloendothelial system in the kidney and spleen and, in some species, in the atrium of the heart. However, teleost fish do not possess Kupffer cells in the liver. Monocytes and macrophages are characterized by their nonspecific esterase staining and avid phagocytic activity. The latter is enhanced by complement and specific antibody, indicating the presence of opsonin receptors on these cell types. Their role in immune responses in fish as antigen-presenting cells and a source of interleukins is not yet well characterized. Channel catfish monocytes have been shown to function as accessory cells required for blood T lymphocytes to respond to the mitogen Con A. Furthermore, this function of monocytes could be replaced by the supernatant obtained from monocyte cultures stimulated with LPS, indicating the production of a 'monokine'. Channel catfish monocytes also perform an essential accessory cell function in the *in vitro* primary antibody response of peripheral blood lymphocytes to both T-independent (TNP-LPS) and T-dependent (TNP-KLH) antigens. In these studies the role of the monocyte in stimulation of antibody-producing cells was replaceable by monocyte culture supernatants, suggesting that other cell types (possibly B lymphocytes) could effectively 'present' antigen in the presence of the monokines.

Fish macrophages can also be activated *in vitro* by exposure to supernatants from mitogen-stimulated lymphocytes, indicating the responsiveness of macrophages to interleukins.

Granulocytes are numerous in the circulation of fish and play an important role in inflammatory responses. The neutrophil is the most common type of granulocyte and is well characterized, bearing

close similarity in cytochemistry to mammalian neutrophils. It is phagocytic but not avidly so and its role in defense against bacterial infection may be to secrete antimicrobial enzymes rather than perform intracellular killing. Granulocytes with the morphological and staining characteristics of eosinophils and basophils are not common in teleost fishes and, where they do occur, nothing is known about their function.

Mast cells with precisely the same characteristics as in mammals do not appear to exist in fish. However, a granulocytic cell with a connective tissue distribution similar to that of mast cells in mammals does exist and it is believed to be the analog of mast cells. This cell possesses eosinophilic or PAS-positive granules and ultrastructurally resembles mast cells. They have been termed eosinophilic granular cells (EGCs). *In vivo* degranulation can be induced by certain bacterial toxins as well as typical mast cell degranulating agents such as compound 48/80 and Con A. Degranulation is associated with darkening in skin color of the fish, some loss of equilibrium, swelling and vasodilatation of the intestine and a return to normal by 24 hours. Degranulation is a noncytotoxic event with regeneration of granules by 48 hours. The physiologic changes associated with degranulation were blocked by prior treatment with the antihistamine drugs promethazine and cimetidine but, unexpectedly, so was the degranulation of the EGCs. In mammals, antihistamines block histamine receptors on target cells but do not inhibit degranulation of mast cells induced by 48/80 or con A.

Natural cytotoxic cells (NCCs) have been identified in a wide range of teleost species but they have not been well characterized and may represent a heterogeneous population of cells. They have cytotoxic effects on a wide range of tissue culture cells, especially those infected by virus, and activity against protozoan parasites has also been demonstrated, suggesting these cells play an important role in defense. NCCs are found in the peripheral blood and in some species have been demonstrated also in the thymus, kidney and spleen. Their activity can be enhanced in the presence of phytohemagglutinin. NCCs are non-adherent to nylon wool, and ultrastructural studies indicate the involvement of at least two cell types which resemble monocytes and lymphocytes morphologically.

The immune response

The basic elements of the humoral and cell-mediated immunity are present in fish but many parameters of these responses are not as well developed as in higher vertebrates. An important aspect of immune respon-

siveness in fish is temperature dependency. Different species of fish inhabit waters with very different natural temperature ranges and their physiologic responses are well adapted to these ranges. At temperatures low in the natural range a particular species of fish will respond immunologically very slowly, if at all, to an antigenic stimulus. Thus at 4°C the immune response of trout (a temperate water species) is very slow, while at 12°C the response is maximal. In contrast, the warm water carp has an optimal response at 22°C and is virtually immunosuppressed at 12°C.

Fish produce only a single class of immunoglobulin (Ig), which resembles mammalian IgM in molecular structure. However, while mammalian serum IgM is most frequently a pentameric molecule, that in the serum of teleosts is tetrameric and, in some species, monomeric. A secretory form of IgM has been characterized from the bile and mucus of skin and gut in a few species where it occurs in a dimeric form. These and other data indicate that local (secretory) and systemic responses exist in fish. Evidence for structural heterogeneity in fish IgM heavy and light chains is growing: for example, the existence of two forms of L chains which parallel the κ and λ chains of higher vertebrates and the different molecular masses of H chains among serum, bile and mucus Ig. Recent studies with monoclonal antibodies have revealed the existence of three forms of H chain in catfish serum Ig. Fish IgM appears to be capable of performing all of the functions for which the different mammalian Ig isotypes show specialization, e.g. complement activation and opsonization, and it is possible that these functions in fish may be carried out by different specialized subclasses of IgM. The kinetics of the *antibody response* in fish are similar to those of higher vertebrates but the lag phase is somewhat longer (10–15 days) and peak titers may take up to 5–6 weeks to be reached. Antibody persists for fairly long periods, particularly in primitive species such as trout, where persistence for up to 1 year has been reported for antibodies to certain bacterial antigens.

The correlates of cell-mediated immunity are present in fish – for example, mixed leukocyte reactions, macrophage migration inhibition, interleukin production inducing macrophage activation, delayed type hypersensitivity and acute skin rejection responses. Allogeneic restriction of antigen presentation and the existence of MHC genes in fish have been demonstrated.

Evidence for lymphokine production in fish is well established and while no fish cytokines have yet been purified, evidence indicates the existence of several types, for example interferon γ (IFN γ), interleukin 1

(IL-1), IL-2, colony-stimulating factor (CSF), transforming growth factor β (TGF β) and tumor necrosis factor.

Immune memory has been demonstrated in fish for both humoral and cell-mediated immunity. However, the magnitude of antibody titers reached in the secondary response as compared with the primary response in fish is generally lower than in mammals (about 10-fold higher, compared with 100-fold in mammals). Of course, fish differ from higher vertebrates in that there is no shift of antibody isotype from IgM to IgG. Typically, memory induction takes longer to be established in fish (3–6 months) than in mammals and persists for 8–12 months after primary stimulation. Induction of memory appears to be temperature dependent. Generally speaking, immune responses in fish which involve the stimulation of T lymphocyte functions appear to require temperatures fairly high in the natural range of a particular species, while antibody production itself can occur at lower temperatures. Some doubt has been expressed as to the ability of temperate species, such as trout, to mount a significant secondary antibody response and it may be that these species rely instead upon prolonged production of antibody to provide long-term protection.

Immune tolerance has been demonstrated in several species of fish. The carp anti-BSA response has been suppressed by intravenous injection of soluble BSA. The induction of tolerance at high temperature was dependent upon the route of injection (intravenous) and not on the dose, while at low temperature it depended both on the intravenous route and high dose. Tolerance in these experiments lasted at least 16 months. Evidence also exists for induction of short-term tolerance by exposing very young fish to certain antigens.

Vaccination of fish

Since the great expansion of fish farming, which began in the early 1970s, there has been much interest in vaccinating fish against the principal bacterial and viral diseases. Effective vaccines have been developed to many fish diseases but only a few have achieved commercial production. The cost constraints on commercial application principally relate to the size of the fish requiring protection and the methods available for effective administration of a vaccine. There are three methods of vaccinating fish: injection, immersion and oral. Many vaccines are only effectively delivered by injection and this method is impractical for small fish (under 15 g). Presently there are only a few vaccines available commercially. These are against important bacterial dis-

eases of farmed salmonid fish, i.e. enteric redmouth (ERM) caused by *Yersinia ruckeri*, vibriosis caused by *Vibrio anguillarum*, cold-water vibriosis caused by *Vibrio salmonicida*, and furunculosis caused by *Aeromonas salmonicida*. These vaccines are effectively delivered by both injection and immersion administration.

Injection vaccination appears to be the most effective means of stimulating protective immunity. The method allows the use of adjuvants but it has a number of disadvantages: it requires fish to be handled and anaesthetized, which are stressful events; it is impractical for small fish; and it is labour and time consuming. Nevertheless, when the disease risks are high injection vaccination is cost effective and frequently practised. Recently, injection machines have been marketed.

Immersion vaccination has proved very useful for a number of bacterial vaccines. These vaccines are formalin-killed broth cultures which are diluted in water and the fish are immunized simply by immersing them, with the use of a hand net, for up to 1 min in the vaccine. It is believed that the vaccine is taken up mainly through the gills. The technique is very useful for vaccinating small fish with the minimum of handling.

Oral vaccination is the method of choice because it does not require the fish to be handled and in this respect is the only method which could be applied to extensive fish farming where the fish are not handled until slaughter. Unfortunately, this method has not proved to be very efficacious. Nevertheless, there is still much interest in the method because administration of vaccines by anal intubation appear to be very effective. Recent studies have demonstrated that, in carp and trout, the hind intestine is capable of antigen absorption, which results in effective stimulation of protective immunity; thus, interest is now centered upon microencapsulation of oral vaccines to protect the antigens during their passage through the anterior gut and to release them in the hind gut.

There is a growing interest in using recombinant DNA technology to achieve cheap production of viral and parasite antigens for use in vaccinating fish. There is still very little known concerning the nature of the protective antigens or the protective immune response to most vaccines used in aquaculture: the future of fish vaccination will probably depend very largely upon identifying the nature of these so as to optimize the production of vaccines and their effective administration. Fish farming is rapidly becoming a major industry in many countries of the world and there will be a growing need for vaccines to control disease in a wide range of fish species in the future.

FLAVIVIRUS, INFECTION AND IMMUNITY

Thomas J Chambers, Department of Molecular Microbiology and Immunology, St Louis University Health Sciences Center, St Louis, Missouri, USA

The family Flaviviridae includes 69 viruses, the majority of which are transmitted by mosquitoes and ticks. Some are zoonotic agents without known arthropod vectors. More than half of these arboviruses have been associated with human disease. The viruses are distributed worldwide in many distinct ecological patterns, and cause three principal syndromes in humans: febrile illness, encephalitis and hemorrhagic fever. The most important viruses are yellow fever (YF), dengue (DEN), Japanese encephalitis (JE) and tickborne encephalitis (TBE). Flaviviruses are enveloped RNA viruses containing a single linear RNA molecule of approximately 10 000 nucleotides, encoding three structural and at least seven nonstructural proteins (Figure 1). The genome is encapsidated by a core protein and enclosed within a lipid envelope containing the M and E proteins. The E protein is critical for infection and immunity, as it contains cellular receptor-binding determinants, a membrane fusion activity and epitopes for neutralizing antibodies.

Characteristics of flaviviruses

Flaviviruses have been traditionally classified on the basis of antigenic cross-reactivity of the E protein, including both neutralization and hemagglutinating properties. Group-reactive, serocomplex-reactive and type-specific determinants have been described, although these underrepresent the antigenic relation-

ships of many viruses. Eight different antigenic groups can be defined (Table 1).

YF, the prototype of the flavivirus family, is antigenically distinct and classified with 16 other viruses which are serologically unrelated to defined groups. YF is a zoonotic disease which causes hemorrhagic fever in subsaharan Africa and tropical regions of South America. Up to a few hundred cases in South America, and several thousand cases in Africa have been reported annually.

JE virus, the prototype of the JE serogroup, is distributed throughout many countries of Asia, and is responsible for 30 000–40 000 cases annually in China, with an associated mortality rate of approximately 30%. It is the most important arthropod-transmitted viral encephalitis worldwide. Other JE serocomplex viruses are also important human pathogens.

The tickborne encephalitis (TBE) virus complex includes 14 viruses, of which eight are known human pathogens. TBE occurs in regions of Europe and the former Soviet Union where the ixodid tick vector is prevalent and is a serious disease with variable mortality depending on the subtype of virus and age of onset in clinical cases. Two viruses within the TBE complex cause hemorrhagic fever.

The dengue (DEN) antigenic complex includes four serotypes associated with dengue fever (DF), and dengue hemorrhagic fever/shock syndrome (DHF/DSS). Together these cause large epidemics

Figure 1 Structure of the flavivirus genome and processing of the viral polyprotein. At top is the organization of the genome common to all family members. Cap, 5' cap structure; 5' NTR and 3' NTR, untranslated regions of the genome; ORF, open reading frame. Symbols indicate proteases involved in processing viral proteins as follows: solid diamonds, host signalase; single open arrows, viral protease; question mark, uncharacterized host endoplasmic reticulum protease; double open arrows, host Golgi protease. Asterisks indicate *N*-linked glycans on prM and NS1. The viral structural proteins (C, capsid; prM, precursor to M; E, envelope) are shaded light, and nonstructural proteins (numbered 1–5) are unshaded. Hydrophobic regions of the polyprotein are shaded dark. (From Fields *Virology*, 3rd edn (1996), Lippincott-Raven Press, Philadelphia, courtesy of Dr Charles M Rice.)

Table 1 Antigenic groups of the flaviviruses

Group	Members	Principal viruses	Arthropod vector	Disease in humans	Significance ^a	Vaccine available
Tickborne encephalitis (TBE)	12	Russian spring summer (RSSE); Central European (CEE); Omsk hemorrhagic fever (OHF); Kyasanur Forest disease (KFD)	Ticks	Encephalitis (RSSE, CEE); hemorrhagic fever (OHF, KFD)	Moderate	TBE, KSD
Rio Bravo (RB)	6	Rio Bravo (RB)	None	Febrile illness (RB)	Minor	
Japanese encephalitis (JE)	10	JE; St Louis (SLE); Murray Valley (MVE); West Nile (WN); Kunjin (KUN)	Mosquito	Encephalitis (JE, SLE, MVE, KUN); febrile illness (WN)	JE: major; others: moderate	JE
Tyulenyi	3	Tyulenyi	Tick	No		
Ntaya	5	Ntaya	Mosquito	No		
Uganda	4	Uganda, Brazil (B), Edge Hill (EH)	Mosquito	Febrile illness (B, EH)	Minor	
Dengue (DEN)	4	DEN serotypes 1–4	Mosquito	DF; DHF/DSS	Major	No ^b
Modoc	5	Modoc (M)	None	Aseptic meningitis (M)	Minor	
Ungrouped	17	Yellow fever (YF) Rocio (R), Zika (Z), Wesselsbron (W), Ilheus (I)	Mosquito (YF, R, Z, W, I)	Hemorrhagic fever (YF); encephalitis (R); febrile illness (Z, W, I)	YF: major; others: moderate-minor	YF

^bDengue vaccine is under development (see text).

throughout tropical regions of Asia, Africa, Australia and Central and South America. Estimates of the annual global disease burden include up to 100 million cases of DF and 250 000 cases of DHF. Primary DF is an acute self-limited febrile illness which induces protection against homologous but not heterologous serotypes. Sequential infections can pro-

duce severe disease (DHF/DSS). The incidence of DHF has risen dramatically in Asia, and it now poses a serious public health threat in the Western Hemisphere due to introduction of multiple serotypes and re-establishment of the *Aedes aegypti* vector throughout this region.

Nucleotide sequence comparisons of flavivirus E

proteins have been used to construct phylogenetic trees which provide a more uniform classification scheme than those based on serology, as well as insight into virus evolution. Flaviviruses may have originated in central Africa from a rudimentary insect virus, the cell-fusing agent, several thousand years ago. Westward spread into the Southeast Asian basin and across the former Soviet Union and Europe was accompanied by emergence of many encephalitic viruses of the tickborne and mosquito-borne groups. Emergence of hemorrhagic fever caused by YF and DEN probably occurred within the last 500 years, with adaptation of these viruses to lymphoid cells and changes in their animal reservoirs and mosquito vectors. Nucleotide sequence comparisons have also revealed geographic variation of DEN, JE, and YF viruses. The relationship of genotypic differences to epidemiology and pathogenesis is under investigation, particularly for DEN for which a serotype 2 strain has been associated with recurrent outbreaks of DHF in the Americas.

Host factors can affect susceptibility to flavivirus infection. Resistance to flaviviruses in mice is associated with an autosomal dominant allele (the *Flv* locus) which restricts viral replication by an unknown mechanism. This may involve cellular proteins which bind to stem-loop structures in the 3' untranslated region of viral RNA. Other host factors relevant to disease susceptibility include the haplotype-restricted immune responses observed in mouse models and the association of certain HLA alleles with occurrence of severe dengue infection among humans. Virus-specific proteins involved in virulence have been inferred from nucleotide sequence com-

parisons of virulent and attenuated strains, such as the Asibi strain of YF and its vaccine derivative, YF17D. The most-well characterized is the viral envelope (E) protein. Determinants within other regions of the genome, including the 5' and 3' untranslated regions, and the prM and NS1 proteins can also affect virulence properties. Whether these act by direct effects on viral replication or by affecting interactions with host factors requires further study.

Solution of the three-dimensional structure of the E protein for TBE virus has provided a model for all flavivirus E proteins. This protein is oriented on the virion surface as flat elongated dimers, each subunit of which contains three distinct domains (Figure 2). Epitopes for neutralizing antibodies are distributed widely over the protein, and are predominantly conformation dependent. Domain I (central domain) contains a conserved glycosylation site and is connected to the long looped structure of domain II (dimerization domain) by a hinge region. The distal end of domain II contains a conserved sequence proposed to be a fusion peptide. Fusion is associated with low pH-induced conformational changes within domains I and II that lead to reorganization of subunits as a trimer and changes in epitopes for neutralizing antibodies within these domains. Domain III has the fold of an immunoglobulin constant domain and contains a putative cellular receptor attachment site. The mechanisms of antibody neutralization probably involve interference with either the dimer-trimer transition, or virus-cell interactions governed by domain III. Amino acid residues which affect virulence have been studied with monoclonal

Figure 2 Structure of the flavivirus E (envelope) protein. Shown is the ribbon diagram of the model derived from the X-ray crystallographic structure of the soluble fragment of the TBE envelope glycoprotein (Rey *et al* (1995) *Nature* 375: 291–298). The figure depicts the antiparallel arrangement of two individual subunits (shaded light or dark) of the dimer as would be seen from a top view. Domains are as referred to in the text. (Courtesy of Dr Franz X Heinz.)

antibody neutralization-escape mutants, host-restricted mutants, virulence revertants and viruses engineered with molecular clones. Such residues cluster to specific sites within the E protein, which include the lateral surface of domain III (cellular receptor binding domain), the external surface of domain I, the domain I–II interface (hinge region), the distal loop of domain II (fusion peptide), and the adjacent conserved N-linked carbohydrate attachment site. It is presumed that substitutions at these sites affect early virus–cell interactions during entry and uncoating.

Immune responses to flaviviruses

Immune responses to flaviviruses have been investigated in both encephalitic and hemorrhagic models of disease. Although the mouse has been used for studies of the encephalitic viruses, there is no animal model for dengue and studies of YF pathogenesis require nonhuman primates. Understanding of these latter two diseases is therefore limited. In mice, virus entry into the central nervous system (CNS) probably occurs by hematogenous dissemination, based on correlations between viremia and the onset of encephalitis and the observation that damage to the blood–brain barrier facilitates neuroinvasion. Such damage has been demonstrated in dengue infection of mice. Susceptibility to encephalitis in mice is age dependent and may involve both immaturity of the blood–brain barrier in young animals and a greater sensitivity of developing neurons to virus-induced cell death. Although flaviviruses are typically cytopathic viruses in mammalian cells, both DEN and JE can induce apoptosis in certain cell types *in vitro*. The relationship of this phenomenon to pathogenesis in animal models and natural infections requires further study.

Adoptive transfer, immune abrogation/depletion experiments and studies in immunodeficient animals have been used to infer the roles of immune responses against flaviviruses. Important virus–host interactions have been described at the level of non-specific host defense systems. Macrophages are involved in clearance of viremia, but antiviral functions and susceptibility to infection may depend on their activation state and levels of virus-specific antibodies. This is particularly relevant during dengue infection (discussed below). *In vitro*, TBE virus-infected macrophages have been shown to be impaired in antiviral effector systems such as production of nitric oxide, which has been reported to have antiviral activity against flaviviruses. Impairment of natural killer (NK) cell function is associated with West Nile (WN) virus infection and may result from induction of class I antigen expression on

infected cells. This effect has been proposed as a viral strategy for early immune system escape and subsequent cytotoxic T lymphocyte (CTL)-mediated release of virus from infected cells.

Virus-specific antibody responses have been clearly shown to provide protection against flavivirus disease. Antibodies to the E protein are protective in a variety of animal models, and are probably the major component of immunity in natural infections. Prior flavivirus infections are believed to ameliorate or protect from subsequent infections with heterologous viruses by stimulating group-specific antibodies. This may partially explain the failure of YF to cause disease in Asia, where dengue virus is widely prevalent. The flavivirus NS1 protein also induces protective antibodies. Active immunization with NS1 or passive administration of antibody can provide varying levels of protection. NS1 is found as cell surface and secreted forms, including oligomers which contain multiple conformation-dependent epitopes. Protection by anti-NS1 immunoglobulin G (IgG) is dependent on an intact Fc portion and is governed by antibody isotype, but the mechanism is not known. Cell surface NS1 can mediate complement-dependent lysis of virus-infected cells, although no requirement for complement during protection *in vivo* has been demonstrated. Antibody-dependent cellular cytotoxicity (ADCC) has been observed for dengue virus and is proposed as a possible mechanism.

The functions of specific T cells during protection against encephalitis remain unclear and the balance of antibody versus cell-mediated immune responses may influence the occurrence of disease within the CNS. T cells adoptively transferred into unimmunized mice can protect against lethal encephalitis, and both nude and SCID mice are susceptible to flavivirus strains which are nonpathogenic in normal animals. This suggests that cellular immunity is required for control of infection. Although both NK cells and virus-specific cytotoxic lymphocytes have been recovered from WN-infected mouse brain, their cellular targets and antiviral functions within the CNS have not been directly demonstrated. A requirement for both CD4⁺ and CD8⁺ T lymphocytes for protection against JE in mice has been reported, but the effector functions of these T cells *in vivo* are also not known. This is a relevant question because of the possibility of flavivirus persistence, which may occur in animal infections and has been suspected in some cases of chronic CNS disease in humans. Both CD4⁺ and CD8⁺ T cells have been detected in human brain during JE infection, and both IgG and immunoglobulin/virus complexes have been found in human cerebrospinal fluid. This suggests that neu-

tralization by virus-specific antibody is an important protective mechanism within the CNS, but cellular immune responses may also be required for virus clearance.

Molecular determinants of virus-specific immunity have been best studied for members of the JE serogroup (WN, JE, MVE and KUN) and the DEN viruses. Flavivirus-specific CTLs have been demonstrated in many mouse models, and cross-reactivity of such responses against related flaviviruses has repeatedly been observed. Antigenic determinants involved in CD8⁺ CTL activation and lysis have been studied in mice using KUN virus. Determinants within the nonstructural proteins NS3 and NS4A/4B induced the strongest responses, many of which were cross-reactive with the related virus WN. Although few overall determinants are involved, the fine specificity of responses is markedly haplotype restricted. Despite cross-reactivity at the level of target cell recognition, this does not necessarily apply to the induction of memory CTL responses in response to heterologous viruses. The implications of these findings for cross-protection versus induction of immunopathology during sequential flavivirus infections have been emphasized. Studies on the molecular basis for murine CD4⁺ class II-restricted responses for KUN revealed a predominance of reactivity only to the structural and NS5 proteins. Haplotype differences in both the levels of responses and the efficiency of different antigen-presenting cells for induction of T cell proliferation have also been described. If these observations apply to human T cells, then it is likely that detailed investigation of the HLA allele-specific responses to flavivirus antigens will be needed to fully understand the pathogenesis of encephalitis and guide the development of novel vaccines.

Virus-specific immune responses to dengue infection have been studied in mice and humans. Dengue is thought to be an immunopathologic disease (Figure 3), with its most severe form, dengue hemorrhagic fever and shock syndrome, dependent upon antibody-enhanced infection of mononuclear phagocytes involving Fc and possibly complement receptors. Cross-reactive antibodies induced by prior infection with a heterologous serotype are believed to enhance secondary dengue infections when present at subneutralizing levels, leading to a large virus burden in the monocyte/macrophage. Primary dengue infection also sensitizes serotype cross-reactive memory T cells for activation during the secondary infection, resulting in the release of inflammatory cytokines which promote the development of a capillary leak syndrome. In mice, CD4⁺ and CD8⁺ T cells having a variety of specificities (serotype-specific, serotype and flavivirus cross-reactive) are generated in

Figure 3 Model of the immunopathogenesis of dengue hemorrhagic fever and shock syndrome (DHF/DSS). Antibody-dependent enhancement of secondary dengue virus (V) infection by heterologous cross-reactive subneutralizing antibody results in a high virus burden in the critical target cell, the monocyte/macrophage. Interferon γ production by CD4⁺ and CD8⁺ memory T lymphocytes induces Fc receptor and MHC antigen expression in conjunction with macrophage activation, augmenting virus infection and antigen presentation (APC). Lysis of macrophages occurs by virus-specific cytotoxic T lymphocytes (CTL) restricted by both MHC class I and II antigens. Production of TNF α by T cells and macrophages, together with other pro-inflammatory cytokines, contributes to the capillary leak and hemorrhagic diathesis that are characteristic of severe dengue infection. (Based on studies reviewed in Kurane I and Ennis F (1992) Immunity and immunopathology in dengue virus infections. *Seminars in Immunology* 4: 121–127.)

response to dengue infection. Similar findings have been obtained with human T cells. Both dengue virus-specific CD4⁺CD8[−] and CD4[−]CD8⁺ cytotoxic T cell responses capable of lysing virus-infected cells have also been demonstrated. Although many viral proteins contain CTL epitopes, NS3 in particular encodes immunodominant epitopes which can drive cross-reactive CTL responses. CD4⁺ T lymphocytes can also be stimulated with dengue antigen to produce interferon γ (IFN γ). The model which incorporates all of these findings proposes that IFN γ up-regulates Fc receptor and MHC antigen expression on activated monocytes/macrophages, increasing

viral burden and antigen presentation, and leading to cytotoxic lysis by dengue-sensitized memory T cells. The multiple serotype cross-reactivities and numerous T cell epitopes demonstrated in humans supports the concept that memory responses are primed for extensive activation during secondary infections. Elevated markers of T cell activation have been shown during early dengue infection in humans, including sCD8, sCD4, sIL-2, and sTNF α receptors, and IFN γ . The source of the proinflammatory cytokines and the role of the T cell responses in providing protection rather than deleterious effects during dengue pathogenesis remain important questions.

Vaccines against flaviviruses

Vaccination against flaviviruses will remain an important public health measure because it is unlikely that these viruses can be eradicated from their animal reservoirs or arthropod vectors. Vaccine for yellow fever (YF17D strain) was the first available live-attenuated vaccine for this family. Derived by serial passage of its virulent parent in cell culture and eggs, YF17D is a safe, highly effective vaccine capable of inducing long-lasting protection. Yellow fever vaccination has been proposed as part of the World Health Organization (WHO) expanded program of immunization to control recurrent epidemics in Africa.

JE, DEN and TBE are also major targets for vaccine development. For TBE, a highly purified formalin-inactivated vaccine is available, which is very effective and has few side-effects. An immunoglobulin preparation against TBE is also used in Europe for pre- and postexposure prophylaxis. Products which have been used for vaccination against JE include both inactivated and live-attenuated viruses. The Biken vaccine, which has been available since the 1960s, is an inactivated preparation purified from mouse brain. Other inactivated vaccines have been developed and used locally in Asian countries. The JE SA14-14-2 vaccine is a live-attenuated virus used extensively for human vaccination within China, but is not currently approved by the WHO.

Vaccine development for DEN has been a major priority for many years but remains problematic because high levels of neutralizing antibodies against all four serotypes are required to prevent the occurrence of DHF/DSS. The most promising candidate is a live-attenuated tetravalent vaccine developed in Thailand and currently undergoing evaluation for human use. Alternatives, such as engineered cDNA clones encoding attenuated viruses, subunit vaccines incorporating the E or NS1 proteins, recombinant vector systems and subviral particles incorporating

the prM and E proteins are under investigation. T helper epitopes capable of priming antibody responses have been identified within flavivirus E proteins, suggesting that synthetic peptides may also have value as vaccines or vaccine adjuncts.

DNA vaccination for flaviviruses has not been widely studied but protective immunity generated by recombinant plasmids encoding the prM and E proteins has been reported. There is a definite need to further investigate the cellular and molecular requirements for induction of solid protective immunity against these viruses in order to understand to what extent these various approaches will be useful. Although only a handful of flaviviruses are now targeted for vaccine development, emergence of new ones in the future may change this situation.

FLOW CYTOMETRY

Mario Roederer, David R Parks, Leonore A Herzenberg and Leonard A Herzenberg,
Department of Genetics, Stanford University, Stanford, California, USA

History

By the time the prototype of the fluorescence-activated cell sorter (FACS) went into operation (at Stanford in the early 1970s), immunofluorescence studies with the light microscope had already demonstrated that lymphocytes could be broadly subdivided according to whether they expressed surface immunoglobulin (Ig) or surface Thy-1. These visually-defined subpopulations, which we now know as B cells and T cells, were presumed to be responsible for different lymphocyte functions; however, the lack of methods for cleanly separating one subpopulation from the other confounded attempts to establish this point.

During the next few years, while the FACS was undergoing its initial metamorphosis into a commercially-available single-laser instrument, a variety

of physical and immunocytotoxic methods were developed that could selectively deplete B cells, T cells or T cell subpopulations from a cell suspension; for example, passage through nylon wool, passage through an affinity column, or complement-dependent killing with antibodies to distinctive cell surface molecules. These depletion methods have proven extremely useful; however, they are mainly restricted to depleting unwanted cell types from a population and thus do not provide for the specific isolation of subpopulations, which is necessary for definitively characterizing their functions.

FACS-based cell isolation methods, in contrast, are well suited to this task, as they provide the potential for sorting and testing viable subpopulations. A significant advantage over mechanical separation methods is that the populations isolated by FACS are usually highly pure. Whereas mechanical separations usually result in purities of 60–90% (with the

remaining cells being unwanted subsets), single FACS-separation runs can achieve over 99% purity – with re-sorting resulting in essentially 100% purity. In addition, the electronic control of the sorting in FACS gives the researcher the ability to sort only a single, viable cell – the quickest and most efficient cell cloning technology extant.

The major advantage of FACS-based separations, however, resides in the multiparametric nature of the measurement. A wide array of characteristics can be used, individually or in combination, to define subpopulations. For example, cell size, surface phenotype, mitotic stage, and intracellular levels of enzymes and metabolites. Thus, as the capabilities of this newly-developed instrument became known, it found increasing use in studies of the functional and developmental relationships among subpopulations of lymphocytes, as well as other cells.

In the last decade, the power of the FACS has been utilized for a much greater range of samples than leukocytes. All kinds of unicellular organisms, from bacteria to yeast to paramecia, have been separated by FACS. This technology has also been applied to the separation of subcellular particles: for instance, sorting endosomes, lysosomes or mitochondria. In addition, the FACS has been used to separate individual eukaryotic chromosomes – a technique that has been pivotal in the establishment of chromosome-specific DNA libraries, an important tool in the human genome project.

In recent years, the application of FACS to biology has taken another significant turn – that of single-cell functional characterization. A variety of assays have been developed to quantitate the functional capacity of individual cells by flow cytometry. These include assays for proliferation or cell cycle progression (e.g. total DNA, RNA and protein contents, as well as number of divisions measured by dyes permanently retained by DNA or cellular membranes), activation (e.g. expression of activation markers on the surface of cells), cytokine expression, apoptosis, calcium mobilization, acidification of internal compartments, changes in reduction–oxidation potential, metabolic activity and various enzymatic activities.

The power of these assays by FACS comes through two unique capabilities. First, since the assay is single-cell based, the resulting measurements provide a view of the *distribution* of activities within a population, rather than an average across the entire population. Since few biological processes are homogeneous across all cells, this view can be critical in assessing the true functional nature of cells. Second, the functional assays can be combined with standard immunofluorescence assays to phenotype the cells;

thus, the functional quantitation can be restricted to any desired subpopulation of cells.

While such functional assays are still reserved primarily for the basic researcher, more and more of them are finding clinical utility. As the instrumentation and data analysis becomes routinely automated, these assays progress into clinical settings, such as prognosis in human immunodeficiency virus (HIV) disease. Over the next 10 years, many of these single-cell FACS-based functional assays will become routine in the clinic because they provide information that cannot be obtained by standard bulk assays.

Elucidation of lymphocyte subpopulations by FACS

Much of the early work centered around the characterization of B cell phenotypes, functions and precursor–progeny relationships. The first significant FACS studies in these areas, published in 1972, demonstrated that antigen-binding cells are precursors of cells that secrete antibodies reactive with the bound antigen. Other studies, begun shortly thereafter, demonstrated that the surface Ig molecules expressed on B cells are restricted to individual allotypes and isotypes and that these surface Ig molecules reflect the allotype and isotype commitment of the cell and its antibody-producing (plasma cell) progeny.

By 1976, sorting and transfer studies with Ig allotype congenic mice placed this basic description of ‘allelic exclusion’ in its current context by showing that all Ig heavy chains expressed by an individual B cell or its progeny are encoded on the same Ig heavy chain chromosome (haplotype). These findings, which provided the operational and theoretical framework for a large series of subsequent B cell development studies, also laid the groundwork for current molecular and FACS studies defining the genetic organization of the Ig heavy chain (IgH) chromosome region and the mechanisms involved in IgH gene rearrangements and class (isotype) switching.

FACS contributions to T cell studies during this period were less dramatic, largely because of difficulties encountered in obtaining antibodies (and hence FACS reagents) that specifically detected individual cell surface antigens. At this time, antibodies for use in FACS (and other) studies were prepared from conventional antisera, which typically contain a mixture of antibodies reactive with the target antigens and an abundance of irrelevant Ig that can stick nonspecifically to cells. Anti-Ig reagents, such as those used in the B cell studies cited above, were relatively easy to prepare because Ig-specific antibodies can be bound to (and eluted from) secreted Ig

coupled to an insoluble matrix. Specific reagents for detecting surface determinants other than Ig, however, were substantially more difficult to produce, as they could not readily be isolated by binding and elution methods. By and large, these reagents had to be produced from antisera (or fractionated Ig) from which contaminant antibodies were removed by absorption with appropriate cells. Thus, FACS T cell work proceeded slowly until the late 1970s, when monoclonal antibodies were introduced as FACS staining reagents.

The development of monoclonal reagents for detecting the major T cell surface determinants in mouse and humans went hand in hand with the development of FACS methods for identifying and sorting the major T cell subpopulations. In essence, the availability of highly specific and easily purified antibodies that could be readily coupled with fluorochromes made it possible to use the quantitative expression of cell surface antigens to recognize lymphocyte (and other) subpopulations and to sort these subpopulations to chart their functions.

Initial studies with this monoclonal-based methodology defined the murine Ly-1 (CD5) and Lyt-2 (CD8) lymphocyte surface antigens and characterized the expression of these antigens on T cell subpopulations in mouse spleen, lymph node and thymus. These FACS characterizations were used to discover monoclonal antibodies that detected the human Leu-1 (CD5) and Leu-2a (CD8) homologs of the murine genes (Figure 1). In addition, these early studies used these (and other) monoclonal antibodies to identify and characterize the so-called 'helper/inducer' and 'suppressor/cytotoxic' subsets of human T cells.

At present, nearly all FACS studies characterizing the expression of cell surface antigens are conducted with monoclonal antibody reagents. The shift to this virtually exclusive use of these reagents occurred extremely rapidly and was accompanied by an equally rapid expansion in FACS utilization, particularly in studies of human and murine lymphocytes. Surface phenotypes for helper and suppressor T cell subsets were further defined and new subpopulations within these subsets were identified. B cell FACS studies also prospered and marked advances were made in clinical FACS application. In one striking example, leukemia phenotyping opened the way to a rationalization of treatment protocols that substantially improved patient survival. In another dramatic instance, measurement of helper and suppressor subpopulation frequencies in normal human adults laid the groundwork for the current widespread use of such measurements as an index of disease pro-

Figure 1 Two-parameter FACS: Leu-2a and Lyt-2 expression on (A) human and (B) mouse lymphoid cells. Early single-color FACS analysis, in conjunction with biochemical studies, demonstrated that human Leu-2a, which is found only on suppressor/cytotoxic cells, is expressed in a very similar pattern as the murine Lyt-2 surface antigen. The Leu-2a antigen was detected by indirect staining with SK1 monoclonal antibody supernatant followed by fluorescein-conjugated goat antimouse IgG1. The Lyt-2 antigen on mouse cells was detected by direct staining with fluorescein-conjugated 53-6.7 monoclonal antibody. Both of the determinants are found on 80–90% of the thymus cells (light lines) and 20–40% of the spleen T cells (dark lines). These antigens are now known as CD8.

gression in acquired immune deficiency syndrome (AIDS).

Multiparameter FACS studies

Methods for labeling antibodies with different fluorochromes (e.g. fluorescein and rhodamine) were developed while the FACS was still in its infancy. Fluorescence microscope studies demonstrated that these 'differently-colored' antibodies could be independently detected on the same cell and thus could be used to distinguish subpopulations on the basis of qualitative or semiquantitative correlations in the expression of two or more surface antigens. In essence, these studies showed that lymphocyte subpopulations distinguished initially by the expression (or nonexpression) of one surface marker could be further subdivided according to the expression (or nonexpression) of a second marker, etc.

Developing an array of fluorescent dyes for reagent labeling and efficient FACS systems that could capitalize on the availability of differently-colored antibody reagents produced with these dyes took some time. Early FACS instruments were equipped with a basic two-color capability that allowed quantitative evaluation of the expression of pairs of cell surface markers on individual cells; however, these initial multiparameter studies were severely restricted by the limited dye combinations, the single-laser FACS instruments and the simplistic computer support available at the time. In fact, studies with these early

instruments basically provided a tantalizing glimpse of how valuable multiparameter FACS methods could be; relatively little was actually accomplished with these methods until the introduction of the dual-laser FACS, the phycobiliproteins (phycoerythrin (PE) and allophycocyanin (APC)) and the sophisticated FACS software that together characterize the multiparameter analysis and sorting methods in use today.

Strictly speaking, multiparameter FACS studies

(defined as the measurement of more than one parameter per cell) began with the prototype FACS, which was built with two sensors: one for fluorescence, and the other for low-angle light scatter ('forward scatter'). The forward scatter measurement on this initial instrument was intended solely to signal the arrival of a cell-sized object in the light path; however, studies with cell populations from lymphoid organs soon showed that the forward scatter signal could also be used as a meaningful measure of

Figure 2 Fluorescence spectra of molecules conjugated to antibody reagents. The excitation and emission spectra of eight fluorescent molecules that can be conjugated to immunoglobulins and used in immunofluorescence studies are shown. All eight can be simultaneously and independently measured. Dashed lines, excitation spectra; solid lines, emission spectra. Spectra are uncorrected for detector sensitivity and are scaled for presentation purposes. Also shown are the excitation lines from the 406 nm krypton line, the 488 nm argon line, and the 595 nm dye laser line. Finally, the stippled boxes represent the transmission areas for each of the filters used to detect that fluorescent molecule by FACS.

cell size and could distinguish, for instance, lymphocytes from monocytes. In addition, the forward scatter signals were shown to be useful for discriminating live cells from dead cells, and for excluding ('gating out') dead cells during analysis and sorting. Thus, as the FACS came into use initially for biological studies, two parameters – forward scatter and fluorescence – were routinely measured and recorded for individual cells.

The introduction of methods for measuring two additional parameters – large-angle light scatter ('side scatter') and a second fluorescence color – moved FACS measurements closer to the current definition of multiparameter studies, i.e. those in which at least two fluorescence measurements and one light scatter measurement are taken per cell. Most flow cytometers are now capable of measuring forward and side scatter as well as at least three fluorescence colors. State of the art instrumentation at Stanford is capable of detecting the two scatter signals as well as eight different, independently-quantifiable fluorescence measurements. The advance to such ten-parameter, three-laser instrumentation has required development efforts at a multitude of levels: 1) chemistry – the continuing development of fluorescent dyes with spectra suitable for flow cytometry (e.g. excitation by commonly avail-

able lasers and emission spectra that do not overlap excessively) has made such advances possible (Figure 2, see p. 935); 2) optics – the construction and optimization of a complex array of filters and photomultiplier tubes that can separate the emitted light into its components and accurately measure those components; 3) electronics – the simultaneous collection and processing of ten or more analog signals, digitization, decisions for sorting, as well as distribution to various computer elements for data storage and analysis; and 4) computer software – analysis of this highly multidimensional data requires 'expert' systems software which can automate many of the tasks that are beyond the capacity of the human mind.

Power of multiparameter analysis

The power of these multiparametric analyses is evident from the unsuspected subdivisions their use has revealed in biological systems. Early on, the division of the two major T cell subsets (helper/inducer versus suppressor/cytotoxic) was shown to be possible by the simultaneous measurement of CD4 (expressed on

Figure 3 Four-parameter FACS: T cell analysis of a mouse lymph node. Two-color FACS analysis is routinely used to quantitate helper/inducer T cells and cytotoxic/suppressor T cells in mouse and humans. The 5% probability plots, which are also shown in other figures, contain an equal number of cells between each pair of contour levels. In this figure, three types of cell can be distinguished: those expressing CD4 (helper/inducer); CD8 (cytotoxic/suppressor); or neither (B cells, NK cells and other leukocytes).

Figure 4 Six-parameter FACS: analysis of murine peritoneal cavity cells. Dual laser FACS analysis permits the simultaneous measurement of six or more parameters. The left plot shows the forward versus side scatter profile. The data, which are recorded in list mode, can be 'gated' for live lymphocytes as shown (i.e. only those cells which fall within the box drawn on the forward scatter versus side scatter plot are viewed in subsequent analyses). Cell surface staining profiles in the right panels do not include dead cells or large live cells such as macrophages. The cell surface analysis of the peritoneal cavity reveals an abundance of Ly-1 lineage B cells. The upper panel shows the characteristic IgM versus IgD phenotype: conventional B cells are indicated by the dashed box and the sum of the CD5⁺ and CD5⁻ Ly-1 B cell lineages are indicated by the solid box. The right bottom plot, which is gated as shown by the solid box in the upper panel, distinguishes the CD5⁻ Ly-1 lineage B cells (solid box) from the CD5⁺ 'sister' Ly-1 B cells (i.e. by the expression of CD5). Percentages are reported in terms of the total live lymphocytes, as determined by the forward and side scatter gates. (Courtesy of Dr Aaron Kantor.)

the helper/inducer) and CD8 (expressed on the suppressor/cytotoxic) populations (Figure 3). These distinctions are relatively easy to make, being primarily 'positive' versus 'negative' in terms of expression of a surface molecule. However, many lymphocyte subsets cannot be distinguished so easily. B cells, for example, were thought to be relatively homogeneous. However, initial multiparameter FACS studies conducted with a dual-laser FACS sys-

tem in our laboratory revealed a series of murine B cell subpopulations and lineages with distinctive functions, localizing behavior, developmental patterns, mitogen and lymphokine responsiveness, etc. Furthermore, potentially homologous B cell subpopulations with similar FACS and functional phenotypes have been identified in rat and in humans.

None of the B cell subpopulations/lineages are as yet recognizable by the presence, absence or surface

Figure 5 Nine-parameter FACS: analysis of human peripheral CD8 T cells. The complex heterogeneity of peripheral CD8 T cells in humans is exemplified by a seven-color staining together with forward and side scatter collection. PBMC were simultaneously stained with CD3, CD8, CD28, CD45RA, CD56, CD57 and CD62L. Shown is progressive 'gating' or restriction of the sample by these parameters. Lymphocytes are selected based on the size parameter (top left histogram); CD8 T cells are selected from this subset by coexpression of CD3 and CD8. The second line of plots shows CD45RA versus CD62L expression for (left to right): total CD8 T cells CD57⁻ CD8 cells, CD57⁺ CD8 cells, and CD56⁺ CD8 cells. Based on functional studies, 'naive' versus 'memory' CD8 T cells can be distinguished by CD45RA and CD62L, as shown in the leftmost panel of this series. CD56⁺ and CD57⁻ cells, which are themselves functionally distinct memory subsets, have heterogeneous expression of these markers – some of these cells fall into the 'naive' gate. Thus, unique identification of naive CD8 T cells requires the simultaneous measurement of (at least) six parameters: CD3⁺, CD8⁺, CD45RA⁺, CD62L⁺, CD56⁻, CD57⁻. Another evaluation of the expression of CD56 and CD57 on the naive and memory subsets is shown in the four plots on the lower left. The bar charts represent analyses of these 16 subsets: the frequency within the naive and memory (N/Mem) subsets (upper) and the relative expression of CD28 on cells of each subset (lower). Data sets such as this single sample are so complex that it becomes impossible to satisfactorily analyze by conventional methods (i.e. 'by hand'). Computer programs which can provide automated 'expert'-type analysis combined with nonparametric cluster algorithms will become invaluable, if not necessary, analysis tools.

level of an individual surface marker. Distinguishing these subpopulations requires measurement of at least two surface molecules (detected by differently-colored antibodies) (Figure 4, see p. 936). In fact, some subpopulations are even difficult to distinguish with three fluorescence and two scatter measurements. Thus, although B cell surface marker expression had been studied extensively in single-color analyses, the introduction of multiparameter FACS methods opened an entirely new perspective on the heterogeneity within the overall B cell population.

Nowhere is the power of multiparametric analysis more evident than in studies of peripheral T cell subsets in humans. Similar to the case in mouse, it was recognized early that T cells could be divided into helper/inducer and suppressor/cytotoxic subsets by the surface antigens CD4 and CD8, respectively. However, each one of these subsets is richly heterogeneous, and can be further subdivided by more than a dozen other antigens. The functional roles of these different subsets is poorly understood, primarily because studies have been performed so far using only three- or four-color separations, which does not result in truly homogeneous populations.

Figure 5 (see p. 937), for example, shows how human CD8 T cells can be subdivided into a number of different subsets based on the simultaneous quantitation of six different antigens. The need for this differentiation is exemplified by recent studies of immunopathogenesis in HIV disease (AIDS). Until the early 1990s, the understanding of the changes in the T cell compartment accompanying progression of this disease was rather simplistic: CD4 T cells declined continuously; CD8 T cells initially expanded, stayed high until very late in disease, and then declined somewhat.

However, there were dozens of publications detailing many changes within the CD8 T cell compartment based on two- or three-color approaches (i.e. using one or two colors to identify uniquely the CD8 T cells, and then measuring a single other parameter for those cells). These include increases in HLA-DR, CD38 and CD57 (taken as indications of activation); or decreases in CD26, CD28, CD31, CD45RA, CD62L, and increases in CD45RO, CD11b (taken as indications of a change in the state of differentiation). However, these changes by themselves were usually relatively minor.

Multiparametric analysis began to reveal that, in fact, there are major and consistent changes in the CD8 T cell population that accompany HIV disease – changes that could not be observed by the two-color approaches. For example, naive CD8 T cells are virtually obliterated during progression of

HIV disease. This subset of CD8 T cells is required for any new immune response; it is identified by the coexpression of CD26L and CD45RA. The loss of this important subset was missed for many years because many memory T cells express one or the other (but not both) of these markers; thus, three- or four-color phenotyping was required to reveal this loss. Indeed, when CD8 T cells are carefully phenotyped, it became evident that all 'normal' CD8 T cells were disappearing during HIV progression – exactly like CD4 T cells. The expansion of the bulk population was due entirely to the presence of activated CD8 T cells. Such studies profoundly impact the views of immunopathogenesis of disease.

Multiparametric studies in the near future will resolve much of the confusion surrounding the immunopathogenesis of diseases. These studies will reveal those populations that it is most relevant to quantitate. In addition, the sorting capability of the FACS allows the isolation of pure and homogeneous subsets of cells on which functional studies can be

Figure 6 Analysis of intracellular gene expression. A B-cell line was generated, as a model of differentiation, which upon stimulation expresses κ light chain and turns off the expression of DNA elements controlling the artificially introduced bacterial *lacZ* gene. The histogram (top) demonstrates that *lacZ* (*E. coli* β -galactosidase) expression is reduced following lipopolysaccharide (LPS) stimulation. The β -galactosidase enzyme activity is measured by introducing a fluorogenic substrate, fluorescein digalactoside, into the cells. The contour plots demonstrate a concomitant increase in κ light chain expression, as detected by surface immunofluorescence. (Courtesy of Dr William Kerr.)

performed. These studies are necessary for understanding the pathogenic consequences of changes in the representation of fine lymphocyte subsets.

Molecular and functional studies

More and more frequently, the FACS is used in a wide variety of immunologically relevant molecular studies. These range from measuring changes in the concentration of intracellular small molecules (physiological state or signal transduction events) to quantitating gene expression to chart activation or differentiation events.

In the late 1980s, the FACS molecular tool kit was extended by the development of a technique for measuring the commonly-used reporter gene *lacZ* (β -galactosidase) within the intracellular compartment of mammalian (as well as bacterial and insect) cells. Depending on how it is introduced, this gene can be used either as a marker for lineage and migration

studies or as an insertion probe that can reveal differentiation-dependent enhancer and promoter sites (Figure 6, see p. 938). Furthermore, when introduced as a reporter gene under the control of particular promoter and enhancer elements, it can be used to investigate the mechanisms that regulate gene expression or provide a quantitative indicator of shifts in the activation or differentiation status of individual cells (Figure 7).

Recent developments using inherently fluorescent proteins have provided another tool in the arsenal of FACS-based reporter gene studies. The first of these proteins, termed green fluorescent protein (GFP), has spectral characteristics marginally suitable for quantitation by flow cytometry. An enormous effort has gone into the generation of mutants of the original GFP which have not only increased brightness, but different spectral properties as well. Currently, there are two versions of the GFP which can be simultaneously and independently quantitated. This brings

Figure 7 Correlation of gene expression with cell cycle progression. (A) The β -galactosidase gene expression in a Jurkat T cell line is controlled by DNA enhancer elements bound by a nuclear transcription factor termed NF-AT. Stimulation of T cells results in a signal transduction cascade, including the activation of this nuclear factor. (B) After stimulation for various periods of time up to 12 h, the fraction of cells expressing β -galactosidase activity (and thus having activated NF-AT) increases. β -Galactosidase activity is measured using the fluorogenic substrate fluorescein di-galactoside (FDG). The activation signal is a threshold event: after activation, no further increase in the production of β -galactosidase occurs (compare the positive cells at 2 h with those at 12 h). (C) Simultaneous quantitation of the activation of NF-AT (as revealed by β -galactosidase activity) and cell cycle progression (as revealed by the DNA content of cells) after 2 h of stimulation. Note that cells that have activated NF-AT are more likely to already be in cell cycle progression (S + G₂/M) than unactivated cells. (Courtesy of Dr Stephen Fiering.)

to gene expression analysis the power of multiparameter FACS; that is, the quantitation of different gene elements within individual cells, providing a correlated distribution of expression of those genes in a population (for example, see Figure 8).

The FACS is also a powerful tool for measuring the physiological state of cells. A commonly measured physiological response is the cytoplasmic calcium concentration. Calcium is mobilized from internal stores as well as the extracellular milieu in response to mitogenic signals. Thus, measuring the change in the internal calcium concentration after signaling is an important indicator of the responsiveness of cells, and a predictor of their ultimate proliferative capacity. Figure 9 shows an example of such an experiment. This experiment demonstrates that peripheral blood T cells have a heterogeneous responsiveness in terms of the ability to flux calcium – a heterogeneity which is only evident by combining this experiment with antibody stains to subdivide the populations.

It is very common in flow cytometric analysis to quantitate live versus dead cells. In general, this is most easily accomplished using propidium iodide (PI). PI binds avidly to DNA, but is excluded from DNA in live cells because it cannot cross the mem-

Figure 8 Simultaneous detection of two mutants of green fluorescent protein. Two different mutants (Bex and Vex) of the inherently-fluorescent GFP were selected so that they could be simultaneously and independently measured. In this experiment, cells were infected with a mixture of two different viruses, each expressing one of the mutant GFPs. Most cells were uninfected (expressing neither GFP); some cells were singly infected; and some cells were infected by both viruses (and show expression of both the Bex and Vex mutant GFPs). (Courtesy of Dr Michael Anderson.)

Figure 9 T cell signal transduction measured by calcium translocation. T cells isolated from a healthy individual were 'loaded' with Indo-1, a fluorescent molecule whose spectrum depends on calcium concentration. By measuring and calculating the ratio of two different Indo-1 fluorescences, one which declines and one which increases with increased calcium concentration, an estimate of intracellular calcium content can be made. In this experiment, T cells were also surface stained to determine their differentiation state. They were then stimulated through the T cell receptor, the primary signal for activation of these cells. The figure shows the relative calcium content after stimulating CD4 T cells with antibody to CD3 (dark lines). Cells that coexpress CD45RA and CD62L (and are 'naive' T cells) have a greater capacity to translocate calcium into the cytoplasm, compared with the memory subsets. This observation correlates with the greater capacity of naive T cells to proliferate after such a stimulation. The heterogeneous calcium flux is due to a difference in the CD3 signal transduction pathway: when the cells are stimulated with low concentrations of ionomycin (light lines), the three subsets have indistinguishable calcium mobilization profiles.

brane. Dead cells, on the other hand, have permeable membranes that readily allow PI to enter and bind to the DNA. Thus, inclusion of a small amount of PI in all samples allows dead cells to be excluded from further analysis (or at least separately enumerated). Recently, much interest has focused on pathways by which cells die, in particular that of programmed cell death (or apoptosis). Several assays exist for the quantitation of apoptosis; such an assay is shown in Figure 10. In this example, the cells that have been signaled to die are shown to progress through several distinct stages.

In addition to these examples, assays that measure intracellular pH, reduction-oxidation (redox) potential, mitochondrial activity, RNA content, membrane area, membrane potential and endocytic activity have been developed for use with the multiparametric paradigm of flow cytometry. Changes in these measurements reveal signal transduction events, stress responses, mitogenic responses, etc. – important parameters of the functional capacity of cells. While most of these are used primarily in basic

Figure 10 Discrimination of dying and apoptotic cells. Annexin V is a protein which binds to phosphatidylserine (PTS). PTS is normally not expressed on the outside of cellular membranes, but only on the inside. When cells commit to apoptosis (programmed cell death), one of the earliest events is the loss of this membrane asymmetry in PTS expression. Using fluorescently-conjugated Annexin V, cells early in the apoptosis commitment phase can be identified. During later stages of cell death, the chromatin condenses and binds Hoechst 33342 to a very high degree (note this use in distinction to **Figure 7**, where quantitative binding reveals DNA content); in addition, the Hoechst dye itself is no longer actively removed from the cells. In this figure, Jurkat T cells were induced to apoptosis; after various times they were assayed for Annexin V binding and Hoechst 33342 uptake. There is a clear progression of cells from double-negative, to Annexin V-positive (apoptosis-committed), to double-positive (dead). (Courtesy of Dr Peter Katsikis.)

research, some assays are beginning to find clinical relevance.

For example, oxidative stress has been shown to accompany HIV disease. A FACS assay which can measure intracellular glutathione (the major intracellular antioxidant) showed that lymphocytes in persons with HIV disease are depleted for glutathione – and that this depletion was a predictor of survival in advanced stage disease (**Figure 11**, see p. 942). The combination of surface immunophenotyping and a physiological measurement therefore provides a powerful, clinically relevant parameter. **Figure 11** also shows an example of the *in vivo* quantitation of gene expression of FACS. In this case, the number of CD38 molecules per CD8 T cell (i.e. proportional to the fluorescence of cells stained with phycoerythrin-conjugated anti-CD38 monoclonal antibody) also provides a significant predictor of progression to death in AIDS. Using these two parameters simultaneously is the most significant predictor of lifespan in AIDS patients known to date – far more significant than CD4 T cell counts, the most commonly used surrogate marker.

Clinical relevance has also been ascribed to the quantitative determination of DNA content in lymphocytes. In this case, lymphocyte membranes are disrupted to allow free entry of dyes such as Hoechst 33342 or PI. Quantitative fluorescence measurements easily reveal 2N or 4N DNA content (akin to the example in **Figure 7**). Clinical relevance comes from the observation that many leukemias and lymphomas have aberrant DNA content (aneuploidy). There is an extensive literature on typing such cancers based on DNA quantification.

Finally, the FACS can be used to perform powerful functional assays. FACS-based assays exist which can measure activation, proliferation, cytotoxic activity, apoptosis and cytokine production. Often, the FACS assays are considerably more sensitive than bulk assays. For instance, cytokine production assays can be performed in cell populations stimulated for only 6 h (for example, see **Figure 12**, see p. 942). Bulk assays, which measure cytokine production in supernatant, are technically easier to perform but yield considerably less information, together with greater potential artifact. Bulk assays for cytokine

Figure 11 FACS-measured quantities are powerful prognostic variables in AIDS. Shown are Kaplan–Meier survival plots, which predict the survival of a group of individuals based on a measurement made at an initial time (day 0). (Left) The amount of glutathione (GSB) (the major intracellular antioxidant) was measured in CD4 T cells in 59 HIV-infected adults with advanced disease. Those with high glutathione were far more likely to survive 2 years than those with low glutathione. (Middle) The same individuals were divided on the basis of CD38 expression on CD8 T cells. Quantitating the absolute expression of this molecule, which may reflect the activation state of the immune system, also provides a powerful prognostic of death. (Right) The glutathione measurement and CD38 measurement were correlated to provide an index of individuals who are at high risk for progression to death (i.e. low glutathione and high CD38) versus those who are at low risk. The combination of these two parameters provides the most powerful prognostic value for predicting survival in AIDS patients.

Figure 12 Cytokine profiles of human peripheral T cells. Human T cells were either resting (A) or stimulated with phorbol ester and ionomycin – a powerful activating combination (B). After 6 h, cells were stained for the presence of intracellular cytokines (i.e. the cytokines that are just synthesized and are about to be secreted for effector functions). Essentially no resting T cells are synthesizing cytokines; stimulated T cells will make either interleukin 4 (IL-4) or interferon γ (IFN γ) but very rarely both. Note that a bulk measurement of cytokine production would reveal that both cytokines are made in the population, but would not demonstrate the exclusivity of production on a cell-by-cell basis.

production are typically performed after at least 24 h of culture and provide no information about the distribution of cytokine expression among the cells (e.g. are all cells making the same amount of cytokine, or are only a small fraction of the cells each making a lot?). In the example of **Figure 12**, it would be impossible to deduce from a bulk assay that some cells make only IL-4, while others make only IFN γ .

Again, the real utility of the FACS for making functional assays comes with the combination of

these assays with each other or with immunophenotyping. Thus, not only is it possible to measure how many cells make a particular cytokine, but also what the phenotype of those cells is, and, for instance, what their proliferative capacity is.

Summary

Flow cytometry is a platform upon which dozens of very different, highly-specialized assays can be performed, and provides the capability for performing many of these assays simultaneously. It is this multifactorial nature of the analysis which makes the FACS a unique tool in immunobiology today. The extremely high information density of the data derived from FACS assays is an absolute requirement to begin to elucidate the extremely complex immune system. FACS technology continues to evolve at a fast pace, as it has for a quarter of a century. This evolution includes a continuous infusion of applications into the clinical environment – indeed, the power of FACS for clinical diagnosis and prognosis is already evident from the fact that virtually every modern hospital has at least one of these instruments. The assays being developed in basic research laboratories today, such as those described above, will become routine clinical assays in hospital settings over the next decade.

FLUOROCHROME LABELING

Richard R Hardy, Fox Chase Cancer Center, Philadelphia, USA

Fluorochrome-labeled reagents are an important tool in the analysis of cell surface antigens, both for use in fluorescence microscopy and in flow cytometry. The development of the hybridoma technique for the generation of monoclonal antibodies that can then be employed as fluorescent reagents has greatly aided the delineations of numerous functional subpopulations now known to constitute the immune system.

Furthermore, the workhorses of microscopy, fluorescein isothiocyanate (FITC, fluorescing green) and tetramethyl rhodamine isothiocyanate (TRITC, fluorescing red) have been joined in recent years by new dyes, the photosynthetic accessory proteins known as phycobiliproteins, possessing intense fluorescence and useful excitation/emission spectra. The techniques used for generating fluorescent

reagents using small organic dyes are relatively simple, while those employed for coupling large proteins such as phycobiliproteins are more involved.

Labeling with FITC, rhodamine or biotin

Fluorescein (green) and rhodamine (red) have the advantage of ease in labeling, which involves simply mixing an activated dye reagent with the antibody of interest. In microscopy, filter sets have been developed that permit rapid sequential observation of a double-labeled sample for fluorescein and then rhodamine fluorescence. For microscopy (typically carried out using a mercury arc lamp), fluorescein is not optimally excited, whereas rhodamine is well matched to the arc excitation and so is commonly employed where highest sensitivity is required. In flow cytometry, where lasers are typically used as the source of excitation, fluorescein is optimally excited by the 488 nm line of an argon ion laser and so is usually the dye of choice. Antibodies are typically labeled using the isothiocyanate derivative of fluorescein, whereas rhodamine coupling using the sulfonyl chloride form may be more effective.

The biotin/avidin system has seen extensive application in immunofluorescence analysis. One advantage of this approach is the amplification achieved which permits greater sensitivity in analysis of determinants expressed at low levels. In addition, certain dyes tend to inactivate antibodies (especially monoclonal antibodies) and these can often be utilized more effectively as biotin conjugates. This is particularly true for rhodamine conjugation.

Several years ago, the addition of a second laser on commercial flow cytometry systems introduced correlated two-color analysis. A krypton laser was used to excite x-rhodamine or an argon ion/rhodamine 6G dye laser was used to excite the sulforhodamine dye 'Texas Red'. These systems gave independent signals, both optimized for the indi-

vidual dye, and the latter system in particular permitted very high-quality dual-staining measurements. The obvious disadvantages of this approach were the requirements for a complex, expensive set-up in order to use the fluorescein/Texas Red combination. Such set-ups are now primarily restricted for use in three- or four-color analysis. Some of the more common labels employed in immunofluorescence analysis (from 1 to 4 color) are listed in Table 1.

Regardless of the label employed, certain common features emerge in using fluorochrome-labeled antibodies. One important precaution is the use of control reagents to discriminate between specific and nonspecific staining. Probably the best control is a monoclonal (or polyclonal) antibody of the same isotype prepared in the same way as the specific reagent. Another consideration is that staining can be carried out either with directly labeled reagents or else in multiple incubations (separated by washes) where only the final step is labeled. Multiple steps, while time-consuming, may lead to amplification of staining and so to better separation of labeled and unlabeled populations compared with direct reagents. On the other hand, it is progressively more difficult to carry out dual- or triple-color analysis using second-step reagents (where the second step may react with *all* of the first-step antibodies). Furthermore, care should be taken that directly labeled reagents have enough fluorochrome to achieve resolution, but not so much as to render the antibody 'sticky'. This ratio of fluorochrome : protein must be determined empirically and may be different for flow cytometry as compared with fluorescence microscopy. A final important point is to centrifuge reagents immediately prior to use at very high speed (top speed of a microfuge or 'Airfuge') to eliminate aggregated material from the staining solution, since such aggregates often contribute disproportionately to non-specific background staining.

Table 1 Reagents used in fluorescence labeling

Fluorochrome	Excitation ^a	Emission ^a	Coupling chemistry
Fluorescein	490	520	Isothiocyanate
Rhodamine	520–550	567	Isothiocyanate
Rhodamine ('Lissamine')	520–550	567	Sulfonyl chloride
Sulforhodamine ('Texas Red')	595	615	Sulfonyl chloride
Biotin	N/A	N/A	Succinimide ester
Phycoerythrin (PE)	480–560	570	GMBS/2-IT or DTT/GMBS
Phycocyanin	580–620	640	Same as for PE
Allophycocyanin	600–650	680	Same as for PE

^aApproximate excitation and emission wavelengths given in nm.

Phycobiliproteins

In laser-based flow cytometry, while fluorescein is well matched to the 488 nm argon ion laser line, rhodamine is suboptimally excited by the 514.5 nm argon ion laser line. Furthermore, the wavelengths of fluorescein and rhodamine emissions overlap considerably, not a problem for sequential measurements, but severely limiting simultaneous (correlated) measurements. While careful filtering and electronic compensation have permitted derivation of independent signals from the fluorescein/rhodamine pair, compromises necessitated in accommodating both dyes degraded sensitivity for both stains compared with either one used individually. Thus, the use of dual staining for correlated measurements in flow cytometry was initially restricted to dual-laser instruments.

This difficulty was overcome by the application of phycoerythrin, one of the family of phycobiliproteins, as a fluorescent dye. Phycobiliproteins are found in red algae and cyanobacteria where they serve to transfer energy from blue wavelength light to the chlorophyll photosynthetic system (which is not excited well in the blue). These proteins are well suited as fluorescent dyes because they possess many fluorescent groups (bilins) of several distinct types per protein. This results in a broad excitation range (but with narrow emission) and a very large extinction coefficient compared with small organic fluorochromes.

Phycobiliproteins are divided into three major groups: the phycoerythrins (PEs) with a molecular weight of 240 kDa, having major excitation peaks between 490 and 560 nm and emission at 570 nm; the phycocyanins (PCs) with a molecular weight of 240 kDa, having good excitation from 580 to 620 nm and emission at 640 nm; and the allophycocyanins (APCs) with a molecular weight of 110 kDa, having good excitation between 600 and 650 nm and emission at 680 nm. The orange fluorescence of PE can be excited with reasonable efficiency by the 488 nm line of the argon ion laser, and thus PE can serve as the second dye together with fluorescein in dual-label staining. Phycobiliproteins are available commercially from several sources or, for the more adventurous, can be purified from red algae (for PE) or cyanobacteria (for PC and APC) by simple chromatographic procedures.

Labeling antibody (Ab) with phycobiliprotein (PbP) is more difficult than with small organic reagents such as FITC. Probably the most reliable approach is to use a heterobifunctional cross-linking reagent such as succinimidyl 4-(*p*-maleimidophenyl)butyrate (SMPB) or *N*- γ -maleimidobutyryloxy-succinimide (GMBS). Both of these reagents

carry maleimide groups (reactive with free thiols) and succinimide ester groups (reactive with primary amines). Thus one can couple GMBS to lysine groups on the Ab and introduce free sulfhydryl groups into the PbP with a reagent known as 2-iminothiolane (2-IT). After labeling, the proteins are then mixed (using a 1.5- to 2-fold molar excess of PbP:Ab) and a complex is allowed to form. Small complexes of 1:1 PbP:Ab appear to be best for staining, since they show little nonspecific background. Often the complex does not require separation (this can be tested by staining before attempting separation), but if needed it can be chromatographed on a small hydroxyapatite column or fractionated by gel filtration. An alternative labeling approach that works for certain 'problem' antibodies where the other method fails is to label the PbP with cross-linking reagent and then mix it with Ab that has been mildly reduced (breaking interchain disulfide bonds and generating free sulfhydryl groups) with dithiothreitol (DTT).

Fluorescence microscopy

Fluorescein and rhodamine reagents can be employed individually or simultaneously with appropriate optics. Surface immunofluorescence staining can be performed either on cells in suspension (as outlined in the section on 'Flow cytometry' below) or on frozen tissue sections. After staining, cells are often then fixed with 2% fresh paraformaldehyde (15 min at room temperature) and can then be stored at 4°C for up to 2 weeks. Internal staining is also possible. Cells are applied to a microscope slide either as a 'smear' or, alternatively, by use of a device known as a cytocentrifuge which usually gives a more dense and uniform distribution (particularly important if cells are limiting). The slides are dried and then permeabilized with acetone. Staining is performed in humidified chambers to prevent evaporation, typically for 30 min at room temperature. After washing, stained preparations are mounted in glycerol/PBS containing an antifading compound (commercially available). A major difficulty encountered with fluorescence microscopy (particularly photography) is bleaching, which is somewhat less of a problem with rhodamine than with fluorescein. Finally, it is possible to view Texas Red labeling using rhodamine excitation/emission filters and in dual labeling with fluorescein it often shows better specific labeling than conventional rhodamine. One should also note that dual staining with PE (viewed either with rhodamine optics or specialized PE excitation/emission filters) has seen increasing application in the past few years.

Figure 1 Six-parameter flow cytometry optical system for multicolor immunofluorescence analysis. Cell fluorescence excited by the blue (488 nm) laser is divided into green (FL) and orange (PE) signals, while fluorescence excited by the orange (603 nm) laser is reflected by a mirror and divided into near red (TR) and far red (APC) signals. Blue light scattered at small forward angles (ForSc) and at right angles (90° Sc) is also measured in this system, providing information on cell size and internal granularity.

Flow cytometry: two-color/single-laser

As mentioned above, dual staining in flow cytometry presented a real challenge, one which was not met by the fluorescein/rhodamine combination. Dual-laser systems, especially in combination with a dye laser, gave high-quality correlated immunofluorescence data with fluorescein and Texas Red, but at the cost of optical and electronic complexity and at considerable added expense compared with single-laser instruments. PE is now employed routinely together with fluorescein on a single-laser instrument for two-color correlated analysis. The broad excitation spectrum, large extinction coefficient, and high quantum yield of PE make it a reasonable dye to use in combination with fluorescein at 488 nm excitation. As shown by Figure 1 (blue laser fluorescence), the fluorescences are divided by a

560 nm longpass dichroic reflector, suitably filtered, and then the analog signals are compensated to correct for the small overlap of PE in the fluorescein (FL) channel and the somewhat larger overlap of fluorescein in the PE channel. Data quality compares favorably with two-color staining carried out on a dual-laser system.

Cell suspensions are stained on ice either using directly labeled reagents in a single step or indirectly in multiple incubations separated by washes. Incubations are usually 15–30 min and 2–3 wash steps are probably sufficient to eliminate unbound reagent. Staining medium can be a simple balanced salt solution or even modified cell culture medium and typically contains 5–10% serum (acting as carrier protein) and 0.1% NaN₃ (to prevent capping). If the biotin/avidin two-step staining procedure is employed, it is imperative that the staining medium

does not contain biotin. Dual staining requires that single-label controls also be included to verify that compensation is correct and that there is no interaction between reagents.

Flow cytometry: four-color/dual-laser

Phycobiliproteins also offer the possibility of carrying out three- or four-color correlated immunofluorescence measurements. As shown in Figure 1, a half-mirror splits the fluorescence signals from the two laser spots. Fluorescein and phycoerythrin fluorescences, excited by the 488 nm (blue) laser, are detected and compensated as described above for a single-laser system. Texas Red (TR) and allophycocyanin fluorescences, excited by a tunable dye laser operating at 603 nm (orange), are split by a longpass dichroic reflector at 640 nm, filtered further and then compensated for the somewhat greater overlaps in the TR/APC fluorescence emissions (as compared with the FL/PE combination). This design permits either four immunofluorescence measurements or three immunofluorescence measurements together with propidium iodide (PI) dead cell gating (to eliminate dead cells).

Three- and four-color immunofluorescence have opened up a new era in flow cytometry analysis. Very small populations of functionally distinct lymphoid cells can now be discriminated on the basis of the correlated expression of three or four cell surface antigens. In addition, it is possible to include control staining reagents together with specific reagents and

so determine specific staining on a cell-by-cell basis. Finally, the increased fluorescence signal derivable from phycobiliprotein reagents has eliminated the need for the amplification possible with second-step staining. Thus, these dyes now permit rapid simple quantitation of determinants recognized by monoclonal reagents, even those expressed at very low levels on rare populations in complex mixtures of cells.

FOOD ALLERGY

Jean-Pierre Girard, Department of Agriculture and Fisheries for Scotland, Marine Laboratory, Aberdeen, UK

Untoward reactions to foods – especially cow's milk – were recognized in ancient times by Hippocrates and Galea. However, the first thorough clinical inquiries were undertaken at the beginning of the twentieth century, when chronic diarrhea and anaphylactic-type reactions were observed in babies fed with cow's milk. Later, other types of clinical manifestations were described, e.g. urticaria, eczema, anemia and various respiratory tract and gastrointestinal problems, but the concept of immunologically mediated clinical reactions appeared only progressively, with the discovery of the immunoglobulins and an improved method for the detection of specific antibodies.

More recently, the discovery of IgE immunoglobulins by Ishizaka has considerably increased our understanding of immediate type I hypersensitivity. Having a more accurate means of measuring IgE-mediated reactions, it soon became evident that only a modest part of all the intolerances due to food could be verified by these new *in vivo* and *in vitro* procedures. Consequently, the concept of false food allergy (pseudoallergy) gained in importance and now, besides IgE-mediated reactions, a large variety of mechanisms has been proposed and sometimes verified by appropriate techniques.

The following classification of adverse reactions to food is suggested.

1. Toxic reactions (favism, mushrooms, etc.).
2. Immunologic mechanisms: IgE, IgG and T cell mediated.
3. Food intolerance or pseudoallergy: pharmacologic, enzymatic and undefined reactions.

Disorders associated with food allergens

Gastrointestinal tract

The variety of intolerance reactions due to foods is great. In infancy and early childhood, cow's milk and soya are the major causes of allergic reactions, followed by cereals, eggs and fish. The age of onset is highly variable, from the first days of life (cow's milk) to the age of 2 years. In 90% of cases, clinical intolerance disappears after the age of 3 years. The most common clinical picture is of vomiting, diarrhea and abdominal pain, usually appearing within minutes, or at the most 1–2 h, after ingestion of the food. The period of sensitization is usually short; in some cases, the reaction may occur at the first exposure, probably as a result of previous sensitization by breast milk.

Among the quick-onset reactions, swelling of the lips and tongue, often associated with urticaria and angioedema, are the most common; however, respiratory manifestations also frequently occur, mainly in the form of asthma, cough and stuffy nose. A family history of atopy is often present in such infants and these types of clinical reaction usually correspond to IgE-mediated hypersensitivity, which can be analyzed by means of prick tests and the determination of specific antibodies. Among the slow-onset reactions, food-sensitive enteropathies are the most frequent and also the most difficult to diagnose, especially because of the late onset of the reactions after the ingestion of the incriminated food (sometimes 1–3 days) and the numerous other causes which show a similar clinical picture.

In addition to cow's milk and wheat, which represent more than 80% of all food-sensitive enteropathies in infants, many other foods have been shown on occasion to be the offending agents among older age groups. The major symptoms are diarrhea, abdominal pain, pallor, lethargy, vomiting and loss of weight. Allergic reaction to food is not necessarily evident, and other types of gastroenteropathies need to be excluded. When not recognized early enough, the disease may develop several accompanying symptoms, such as occult intestinal hemorrhage, protein-losing enteropathy, transient gluten intolerance, IgA deficiency and fat malabsorption, among others.

This later-onset gastroenteropathy usually starts during the first 6–8 months of life, when the physi-

ology and the immune competence of the gut are still immature. According to Ferguson, it seems likely that the enteropathy may be due to a type IV hypersensitivity T cell-mediated reaction.

There are no gastrointestinal symptoms due to food allergy which are specific to teenage and adult patients, despite some characteristic differences. For instance, food-induced enteropathy is unusual at this age; on the other hand, gastric and colic symptoms are very frequent. Cow's milk allergy is less prominent as a major allergen. According to large epidemiologic studies, celery, fish, seafood and eggs are the most frequently responsible food allergens among these age groups.

On the other hand, although almost unknown in infancy, among adults reactions to food additives and other chemicals, i.e. false food reactions, are more likely than to the foods themselves. The colon represents one of the major target organs for these various offending agents.

Respiratory tract

Food allergy and intolerance are important triggering factors of asthma. The true frequency is difficult to establish because, in most cases, other allergen families also play a role. Asthma due to a single food allergen is rather infrequent.

According to several clinical studies, the frequency of food-mediated asthma varies from 0.3 to 8.4% of asthma in patients aged under 15 years of age and is somewhat less frequent in adults. It is of interest to note that in studies where correct provocation tests have been undertaken, the percentage of true food-induced asthma is much lower than in those studies in which the diagnosis was made only by means of skin tests and/or the determination of specific IgE. In some cases, the route of sensitization is clearly gastrointestinal (flour, egg, vegetables); in other cases, inhaled allergens are the triggering factors (smell of fish, metabisulfites, garlic, etc.). As mentioned above, food-induced asthma is in most cases only part of a more complex clinical picture. Eczema is a frequent event, particularly in infants; however, urticaria and nasal problems, among other symptoms, constitute a multifocal hypersensitivity syndrome. The diagnosis is difficult because of the coexistence of true allergens with other triggering agents, acting through various mechanisms.

Acute or chronic allergic rhinitis due to food is a problem well known to all allergists; however, its true incidence is a matter of debate. According to various studies it varies from 2 to 25% of all rhinitis.

Additionally, in chronic rhinitis, there is almost always a hyperactive component that can be ascertained following nasal challenge with histamine.

Therefore, the presence of sulfite, nonorganic dusts, and a variety of additives and chemicals may add their effects to those of the suspected food. In such situations, the diagnosis, even with the aid of a provocation test, will often remain inconclusive.

According to various reports, secretory otitis media, particularly in its chronic form, may possess an allergic component in some cases. This is especially true where there exists a known allergy to foods with respiratory and gastrointestinal symptoms. The verification of such a problem is usually indirect, e.g. a clinical improvement being observed following an exclusion diet. According to some studies, up to 80% of patients with secretory otitis media also have an allergic rhinitis; therefore investigation of the rhinitis can eventually help to identify the food component of the otitis.

It is a common observation that some foods can initiate aphthous ulceration in the mouth; however, the true mechanism of these local inflammations is still unknown.

Skin

Eczema, urticaria, vasculitis and angioedema are the major skin reactions observed in food allergy. Urticaria, with its typical histamine-like wheal and flare reaction, is probably the most common reaction of adults to food allergy. About half of these patients develop angioedema simultaneously; angioedema may sometimes be present without urticaria.

Urticaria can be an acute isolated reaction, episodic or chronic. A form of contact urticaria also exists. In most cases, acute urticaria seems to be an IgE-mediated reaction. On the other hand, for chronic and contact urticaria, pharmacologic as well as immunologic mechanisms are involved. Investigation of a chronic urticaria is, unfortunately, deceiving. In no more than 20–30% of these cases can a single specific etiological factor be identified. Drugs such as penicillin and aspirin are the most frequent causative factors. As far as foods are concerned, the testing of patients and the application of elimination diets result in a poor recovery, at most a few per cent. The chances of success are certainly greater among atopic individuals. However, among such patients it is worth looking for histamine-releasing agents present in the food or analyzing the diet for a high histamine content (cheese, seafood, wine, salami, etc.). Also, a strict 2 week additive-free (coloring, preservative agents) diet is sometimes beneficial.

Allergic vasculitis, which is a type III immune complex-mediated reaction, is characterized by a local perivascular inflammation and purpura. Up to now only a few cases have been reported, with food as

the etiological agent. The foods that have been implicated include egg, milk, chocolate, tomato, shellfish, wheat, port and tartrazine.

Atopic eczema is largely a disease of children. This clinical form is rather easy to distinguish from other types of eczema, such as contact eczema. The overall incidence of eczema in early childhood is 10–15%. In only about 2–5% of these cases does the disease persist into adult life. Serum IgE levels are usually elevated – a sure sign of atopy – and other focal allergies such as gastrointestinal problems, asthma and hay fever are often present. However, despite this close association, the role of IgE antibodies in the genesis of eczema is still debatable.

Nevertheless, numerous studies have clearly demonstrated the role of foods (especially milk and eggs) in many cases of atopic eczema. In these clinical trials, many of them double-blind, 10–25% of patients were shown to respond to one particular food. The overall response rate, however, tended to be lower among adults than among children. Also, a lack of correlation has been observed in some cases between the response to diet and the presence of specific IgE antibodies to the food tested.

In this area, most studies have focused on the major allergenic foods, i.e. cow's milk, egg and wheat. In more recent clinical trials, an elemental and oligoantigenic diet has been introduced. Several authors have reported that, beside cow's milk and egg, other foods such as citrus fruit, fish, nuts, tomatoes, lamb, chicken, and colorings and preservatives may be responsible for the exacerbation of eczema among children. Unfortunately, few similar studies have been undertaken with adults.

In conclusion, atopic eczema is a complex clinical problem, the pathogenicity of which is still poorly understood. The following can be used in the management of this disease.

1. This disease is most often observed in atopic individuals.
2. Despite some controversial results, breastfeeding seems to protect infants or delay the onset of the disease.
3. Atopic eczema in breastfed infants may reflect the transmission by human milk of antigens derived from the mother's diet.
4. Specific IgE antibodies to foodstuffs does not necessarily mean a causal relationship with that food.
5. Many foods other than cow's milk have to be considered in the etiology of the disease.
6. Small molecular weight substances such as colorings and preservatives may precipitate attacks of atopic eczema.

7. Important antigens may appear during digestive degradation in the gastrointestinal tract.

Central nervous system

Food-induced migraine is an old problem. As early as 1873, Lieving reported a number of patients whose migraine was due to wine and burnt pastry. Following this study, many researchers reported a relationship between the intake of particular foods and beverages and attacks of migraine. Since then, more sophisticated methods have been introduced to show that there is, for instance, a relationship between the results of specific IgE antibody and skin tests and nontolerated foods, as demonstrated by means of elimination diets and provocation tests.

Patients with food-related migraine represent a subgroup among migrainous individuals. Indeed, they almost all exhibit a variety of symptoms associated with their migraine. Among these symptoms, fatigue and depression are common, as are conjunctivitis, rhinitis, angioedema, urticaria, asthma, irritable bowel syndrome and aching muscles and joints. Frequently the foods (often several foods simultaneously) responsible for the migraine may also play a role in the genesis of the associated symptoms.

Besides IgE antibody-related migraines, there are several biochemical factors associated with the provocation of migraine. Substances such as histamine, tyramine, phenylethylamine, monosodium glutamate, sulfites and phenolic compounds may be associated with attacks of migraine, and the list seems to be growing. Therefore, the diets of migraine patients – especially if they are members of atopic families – should be investigated thoroughly.

When considering a specific food, it is important to appreciate that not only may it induce an IgE-dependent reaction, but it may also act as a non-specific histamine liberator. Furthermore, several allergenic foods are rich in histamine, which may explain some of the clinical problems. Finally, several food constituents in combination could release allergenic mediators. The hyperkinetic syndrome in children has been studied repeatedly, and it has been shown that there is usually a relationship with the diet; however, there is no evidence as to which mechanisms are involved. At present, the best way of identifying which foods are involved is to use an oligoantigenic diet followed by sequential reintroduction of the foods.

Food anaphylaxis

Food anaphylaxis is a severe, sometimes life-threatening generalized reaction. Peanut allergy is the best known example.

The major foods which may induce anaphylaxis are shellfish (crustacea and molluscs), fish, egg, tree nuts, celery and black pepper. These food allergies are often lifelong and reactions can be elicited with minute amounts of the allergen. In most of those cases, oral provocation tests are too dangerous to be performed. Food-dependent, exercise-induced anaphylaxis is also rather frequent in these patients.

Food allergens, additives and chemicals

By carefully reviewing the specialized publications on food allergy, it appears that any food can be potentially allergenic. However, this potential is largely related to ethnic and cultural feeding habits: it is not surprising that allergy to cow's milk or fish is frequent in populations consuming large amounts of these foods. However, with the standardization of feeding habits in the world, exotic or unusual foods may develop their allergenic potential. Kiwi fruit were almost unknown in Europe 15 years ago, but now they have become a frequent allergen. Therefore, common sense dictates that the eating habits of a patient who is suspected of being allergic to a certain food(s) should be carefully noted.

Indeed, the existence of another focal allergy is of major importance. For instance, the knowledge of cross-reactivity between inhaled and ingested allergens demonstrates clearly the frequency of this problem. As an example, the cross-antigenicity between birch pollen and several fruits (apple, pear, peach, cherries, etc.) and vegetables (celery, carrots, parsley, etc.) or the relationship between celery and several spices represent a very complex mosaic of allergenic relationships. This means that unrelated food families might have common allergenic determinants. This does not facilitate the approach of the clinical diagnosis, but at least, for the interpretation of the results, it is essential to be aware of this complexity. However, for some food families for which cross-reactivity is commonly demonstrated *in vitro* or by skin testing, oral challenge results indicate that clinically relevant food allergy is usually specific for one item. This is especially the case for legumes and cereal grain allergy, for which dietary restrictions of the entire food family is rarely needed.

Several other mechanisms may be implicated, the understanding of which is progressing slowly. We are living in an environment which is largely under the influence of chemical substances. According to a recent German study, 140 000 chemicals are now part of our daily life; a number of these may be present in nutrients, either accidentally or in relation to the normal practice of the food industry. Very little information is available about tolerance to most

of these substances. For instance, almost 3000 food additives are used throughout the world, only a few of which have been studied in any detail.

Diagnosis and mechanisms

The major foods responsible for allergic reactions may be related to age as well as specific ethnic and local practices. Food allergens in infants are usually limited to cow's milk, eggs, fish, cereal and soya. In older children the diet is more or less the same as that of their parents; it therefore includes a larger variety of potential allergens. Some of the major criteria used for the diagnosis of food allergy are presented in Table 1.

One of the major steps toward a correct diagnosis is the elimination of the suspected food. If the patient's history does not suggest a specific food, there are two possible approaches:

1. To eliminate successively families of food (milk products, eggs, meat, vegetables, fruits, sweets). The test period should be of at least 2 weeks duration, which is usually sufficient for the symptoms to disappear. Another family of food should be eliminated if no changes are observed.
2. An alternative approach is to introduce a 2–3 week – sometimes longer in eczema patients – oligoallergenic diet, which should include rarely-consumed food such as exotic fruit (no citrus fruit) or cooked vegetables when there is no poliosis present.

There is no standard oligoallergenic diet. It has to be composed according to the feeding habits of each patient. Oral challenge with suspected foods should

be used with caution and under strict medical control because of the risk of an anaphylactic reaction. The best practice is to start with a small amount of food and increase it progressively, over 2–3 days, up to the usual amount. The diagnostic criteria, such as examination of the skin, presence of cough or dyspnea, diarrhea or vomiting or other gastrointestinal tract symptoms, should be carefully observed. A determination of blood eosinophilia is often of great value. A double-blind study is certainly the most objective way of obtaining indisputable results; however, one cannot ignore the difficulties of presenting a large amount of food in an unrecognizable form.

In patients to be challenged, a previous investigation should be performed with the aid of skin tests and the determination of food-specific IgE antibodies (Table 2). However, the food allergens are in most cases crude extracts of whole food, thus increasing the risk of cross-antigenicity and the development of nonspecific inflammatory reactions to skin tests. Besides, there is also a limitation to both the quality and quantity of the allergen coupled to the solid-phase material used for the *in vitro* identification of specific IgE. Therefore, even in atopic individuals, the predictive value of tests for IgE antibodies to foods appears to be rather limited for standard clinical use. Furthermore, types III and IV immunologically mediated hypersensitivities are not infrequent. Unfortunately, we have no reliable laboratory procedures to establish the diagnosis of these types of reactions, with the exception of the lymphocyte proliferation test applicable in the case of a delayed response following oral provocation.

False food allergy (or pseudoallergy)

These types of reaction outnumber the true immunologically mediated ones. Various clinical syndromes are also known to be induced by such reactions, for example chronic urticaria, anaphylactic shock, intermittent diarrhea and irritable bowel syndrome, migraines, rhinitis and asthma. Table 3 lists some of the substances and mechanisms implicated in false food reactions.

Table 1 Major criteria for the diagnosis of food allergy

1. Food allergy is most frequent among atopic individuals, in the presence of IgA deficiency, and in individuals suffering from chronic gastrointestinal problems
2. To some extent, all tissues and organs can be affected by allergenic reactions
3. Nasal, respiratory tract and skin problems can be present without any evidence of gastrointestinal tract involvement
4. The threshold of sensitivity to one specific food is highly variable
5. When the suspected food allergen has been eliminated, the symptoms should disappear
6. A positive elimination diet does not have any significance as far as the mechanism is concerned
7. Following provocation tests, a quick onset of symptoms often means an anaphylactic type of reaction, which usually needs only a small amount of allergenic food
8. Delayed reactions, such as atopic eczema, respond to a provocation test with a delay of 8–24 h

Table 2 Investigations for the diagnosis of food allergy

1. Skin tests (prick) with, where possible, purified allergens
2. Specific circulating IgE antibodies.
3. Double-blind placebo-controlled food challenge
4. Tests to be applied, eventually, before and after oral provocation:
 - Determination of fecal specific IgE antibodies
 - Intestinal permeability test
 - Circulating histamine release test

Table 3 Biologically active substances and mechanisms playing a role in false food reactions

Substances	Type of activity
Histamine	Present in large amounts in some foods; activates specific mediators
Histidine	Present in large amounts in some foods; precursor of histamine
Tyramine	Present in large amounts in some foods; causes pulsatile headache and hypertension
Phenylethylamine	Present in some food; causes migraine
Benzoate	Present in some foods and benzoic acid; causes asthma and rhinitis
Sodium bisulfite	Preservative; destroys vitamin B ₁ ; causes gastrointestinal symptoms
Sulfur dioxide and metabisulfites	Preservatives; cause gastrointestinal tract symptoms, headache, asthma; destroy vitamins B ₆ and B ₁
Monosodium glutamate	Flavor-enhancing agent; causes asthma and the Chinese restaurant syndrome
Food colorings	Especially yellow no. 5 and no. 6; cause asthma and other allergic reactions
Aspirin	One of many possible triggering factors inducing asthma, urticaria and angioedema

The diagnosis of false food allergy is difficult. Amine intolerance, which is frequent in atopic individuals, can eventually be suspected when analyzing the patient's diet. It may coexist with true IgE-mediated reactions. The diagnosis of intolerance to food additives is even more complicated. Besides a thorough clinical history and an analysis of the diet, the first approach is to introduce an additive-free diet, something that is not necessarily simple. Alcohol and coffee, which seem to augment the resorption of small molecular weight substances, should be discarded. Fortunately, additives which are used in small concentrations allow the practice of double-blind oral or sublingual provocation tests in capsules. Three to four concentrations of each substance are usually applied at 2 or 3 day intervals.

Patients who have repeatedly received antibiotics or have a diet particularly rich in sugars and fat might show an invasion of their gastrointestinal tract by *Candida albicans* or *Geotrichum candidum*. This infestation seems to favor allergy as well as pseudo-allergic reactions to foods, and should be treated.

Treatment

One of the major tasks in the management of food allergy is the avoidance of the responsible foods. In practice, this approach is not as simple as it seems. Often, allergy specialists are confronted with patients who have had a poor diet (from a nutritional point of view) for a long time, simply because foods have progressively been eliminated from their diet by their physician on purely subjective grounds. Therefore, it is worth the clinician spending time in controlling the elimination-reintroduction procedure in order to identify for certain the offending foods. Further, the dose-response is highly variable from patient to

patient, several of whom can tolerate a small amount of the food to which they are sensitive, an amount which can be determined by means of provocation tests. The new diet has to be appetizing and complete as far as nutrients, vitamins and minerals are concerned. For this specific aspect, the skill of a dietician is of major importance.

Drug therapy directed against the patient's symptoms is required, whatever the local organ involved. This is especially important in the case of chronic gastrointestinal and colic disturbances.

Drugs

A number of studies have shown that allergic reaction to foods can be ameliorated or prevented by sodium cromoglycate (SCG). This drug seems to be efficient in IgE-mediated reactions as well as in the case of histamine-releasing foods. There is sometimes intolerance to the drug itself. The best way of minimizing this problem is to start the treatment at low doses, increasing it daily to efficient levels by 10–15 days. However, the experience of several clinicians is that after several months of treatment the effect of SCG often decreases and sometimes disappears completely; therefore this therapeutic approach can only exceptionally be considered as a long-term treatment.

The best way of managing the food allergy problem is to introduce the correct elimination diet. If followed for a long period of time (more than 1 year), a relative tolerance to the offending food is frequently observed.

Hyposensitization

This therapeutic approach has never really been evaluated by allergologists, and in most cases there is no real indication for such a treatment. However,

there are two different situations in which such a treatment can be useful, even life-saving:

1. Anaphylactic shock to egg, celery, nuts, fish, milk, etc. is rather frequent in adult patients. Recently, ten such patients were hospitalized and a rush-desensitization procedure was undertaken. The treatment was continued at home. After 3 months of treatment, the offending foods could be tolerated by each patient.
2. Allergy to milk in infants is frequently complicated by an allergy to soya. We suggest an oral hyposensitization regimen beginning with 1:10 000 or 1:100 000 diluted cow's milk. After 3 months of increasing the oral dose daily, 80% of treated children are able to tolerate a glass of milk.

Thus this type of treatment seems to produce a long-lasting tolerance in most patients and is relatively easy to apply.

Conclusions

Allergic reactions and intolerance to food, additives and other chemicals now represent a fascinating and motivating field of research. Despite the fact that knowledge is lacking in several areas of this complex domain, it is actually possible to improve the life of a large number of individuals by simply applying good

clinical practice and a few simple investigative procedures.

FORSSMAN ANTIGEN

Peter F Mühlradt, Immunobiology Research Group, Gesellschaft für Biotechnologische Forschung mbH, Braunschweig, Germany

The Forssman antigen was named after the Swedish pathologist John F. Forssman (1868–1947) who reported, in 1911, that antibodies produced in rabbits against organ homogenates from guinea pigs reacted with sheep erythrocytes, causing hemolysis. The Forssman antigen is thus an example of a heterophile antigen or hapten which occurs in several species. In 1936 Forssman antigen was recognized by F. E. Brunius as a hexosamine-containing lipid. The determinant was later identified as the GalNAc α (1–3)GalNAc β (1–R) disaccharide group. The complete structure of a Forssman-specific glycosphingolipid from horse spleen was published in 1971 by B. Sidiqui and S. I. Hakomori. Forssman specificity was described in many animal species, plants and bacteria. In some species, for example the mouse, Forssman antigen is a developmental and differentiation

antigen. Although it is mostly expressed on the cell surface, there are examples of expression inside cells. Antibodies against Forssman antigen can be used to induce shock in guinea pigs.

Structure, conformation, isolation and detection

Although the concept of the Forssman determinant may have varied over the years since its discovery, originally being more or less synonymous with hemolytic antisheep erythrocyte specificity, the now accepted determinant is a terminal GalNAc α (1–3)GalNAc β (1–R) disaccharide group. This determinant can be linked to a glycosphingolipid residue, as is usually the case in animal cells. The most frequent

structure of such a glycosphingolipid is a member of the so-called globo series:

Information about the nonlinear conformation came from nuclear magnetic resonance. Isolation of Forssman-reactive glycosphingolipids can be achieved by conventional extraction and purification methods in use for glycosphingolipids. Forssman pentasaccharide has also become available through organic synthesis. Various assays for detecting Forssman antigen or Forssman-specific antibodies have been described, ranging from sheep erythrocyte agglutination inhibition to radioimmunoassays or liposome lysis assays. A number of monoclonal antibodies specifically detect the Forssman determinant without cross-reactivity with blood group A or globoside.

Species distribution, cross-reacting antigens from bacteria or parasites

Only certain animal species express Forssman antigen (Table 1). In humans, approximately 20–30% of individuals possess the antigen. Which particular cells are Forssman positive depends on the species.

Table 1 Occurrence of Forssman antigen in tissues from various animal species

Species	Forssman positive
Carp	Yes
Cat	Yes
Cattle	No
Chicken	Yes
Dog	Yes
Frog	No
Goat	Yes
Goose	No
Guinea pig	Yes
Hamster	Yes
Horse	Yes
Human	20–30%
Mouse	Yes
Musk shrew	Yes
Pig	No
Pigeon	Yes
Quail, Japanese	Yes
Rabbit	No
Rat	No
Sheep	Yes
Turtle	Yes

Some strains of gram-negative (*Shigella*) as well as gram-positive (*Pneumococcus*) bacteria carry Forssman specificity. In pneumococci Forssman antigenicity is associated with lipoteichoic acid. Passively acquired Forssman antigen was also found in amastigotes of *Leishmania* proliferating in Forssman-positive murine macrophages; however, here, as in virus grown in Forssman-positive host cell cultures, the antigen was derived from the host cell.

Cellular distribution, role as developmental and differentiation antigen

The function of Forssman-specific cell surface carbohydrate determinants for animal cells, if any, is not entirely clear. However, data from different experimental systems suggest that these carbohydrate structures may play a role in cell adherence and recognition. Thus Forssman determinants appear at certain stages in murine embryonic development, they are involved in laminin adhesion of canine kidney cells, they may play a role in the formation of hematopoietic foci in mouse bone marrow, and they are serological markers for subpopulations of murine mast cells or murine macrophages residing in defined areas of the spleen (Figure 1). At least in macrophages expression of Forssman antigen can be modulated by cytokines.

Forssman glycosphingolipid as a receptor for bacterial adhesins

Bacteria have acquired means of specifically adhering to target host cells via fimbriae. For example, uropathogenic *Escherichia coli* adhere to glycolipid receptors on epithelial cells. The receptor for class III adhesins from such bacteria is the Forssman glycosphingolipid. Other adhesins prefer the underlying globoside structure.

Forssman specificity and disease

Forssman-specific antibodies have been found to be associated with autoimmune diseases such as Graves' disease and Hashimoto's disease. The role of Forssman-specific antibodies in patients with Guillain-Barré syndrome is under discussion. Forssman determinants are also expressed in certain human cancer tissues – for example, in adenocarcinoma of the stomach and colon in individuals whose tissues are normally Forssman negative.

Figure 1 Immunostaining of Forssman-positive macrophages in the red pulp (left) and Thy-1-positive T cells (right) in adjacent sections of a murine spleen. Note the faint Forssman-positive immunostaining of reticular cells in the T cell area.

Forssman shock

Systemic Forssman shock ensues when Forssman-specific antibodies are given intravenously to guinea pigs whose endothelial cells of the lung and kidney are Forssman positive. A complement-dependent reaction leads to bronchioconstriction and pulmonary endothelial lesions. The reaction is used as an animal model to test various drugs against anaphylaxis, thromboxane-mediated bronchioconstriction or thromboembolism.

FRANCISELLA, INFECTION AND IMMUNITY

Arne Tärnvik, Department of Infectious Diseases, Umeå University, Umeå, Sweden

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Tularemia is a zoonotic disease caused by the facultative intracellular bacterium *Francisella tularensis*. There are two predominating forms of the disease: ulceroglandular tularemia which is vector-borne or caused by contact with infected animals, and respiratory tularemia which results from inhalation of contaminated dust. *F. tularensis* occurs in two main biovars: var. *tularensis*, and var. *palaeartica*. *F. tularensis* var. *tularensis* also called type A, is isolated only in North America. It is associated with ticks and rabbits and is highly virulent in humans. Before antibiotic treatment was introduced, mortality was about 10%. *F. tularensis* var. *palaeartica* (type B), which occurs in Asia, Europe, and to a much lesser extent also in North America, is associated with mosquitoes and rodents. It is less virulent in humans. The mortality was less than 1% in preantibiotic times. Biovar type A can be separated from type B by its ability to form acids from glycerol and to split citrulline into ornithine, carbon dioxide and ammonia. As judged from immunodiffusion studies, the two biovars have a similar antigen composition.

Characteristics of the organism and its antigens

F. tularensis is a small coccoid or ellipsoid nonmotile gram-negative bacterium. It has a capsule which can be dissociated from the cell wall by incubation of the bacteria in hypertonic NaCl.

It grows poorly on most ordinary culture media. Growth is, however, well supported on blood agar enriched with L-cysteine and glucose. Chocolate agar, such as used for the isolation of gonococci, also maintains the growth of *F. tularensis*. *F. tularensis* is strictly aerobic, weakly catalase-positive, and oxidase-negative. Carbohydrates are weakly catabolized with the production of acid but no gas. The organism has a characteristic pattern of cellular fatty acids, including long-chain (C20–C26) acids and the hydroxy acids 2-hydroxydecanoate, 3-hydroxyhexadecanoate and 3-hydroxyoctadecanoate.

F. tularensis seems to be unique among clinically important gram-negative bacteria in so far as more than 50% (wt/vol) of its capsule and cell wall are lipids. Accordingly, ether-water extraction is an efficient way to release antigen. The reactivity of immune serum with such an extract is due mainly to carbohydrate determinants, whereas determinants responsible for immunospecific lymphocyte stimu-

lation reside in proteins of the extract. Antibodies to membrane proteins of *F. tularensis* can be demonstrated in immune serum by the immunoblotting technique.

F. tularensis is strongly agglutinated by commercially available antisera. By immunodiffusion of sonicated *F. tularensis* against hyperimmune serum, several antigenic determinants are disclosed. Minor cross-reactions are found with *Brucella*, *Yersinia* and *Proteus*. The only strongly cross-reacting species seems to be *Francisella philomiragia*.

Proteins of *F. tularensis* able to induce cell-mediated immunity reside mainly in the bacterial membranes. According to *in vitro* studies, several membrane polypeptides of the vaccine strain *F. tularensis* LVS induce a T cell response in LVS-vaccinated individuals as well as in individuals previously undergoing tularemia. Experiments with T cell clones suggest that there is a heterogeneity of T cell determinants among these polypeptides.

Immune responses of the host

A strong antibody response to *F. tularensis* is mounted during infection. In diagnostic work, this response is generally demonstrated by use of agglutination techniques, although ELISA can also be applied. Irrespective of technique, the antibodies can be demonstrated at the end of the 2nd or during the 3rd week of disease. The antibodies endure for several years after recovery from tularemia. It should be noted that immunoglobulin M (IgM) antibodies do not appear earlier than IgG antibodies and that IgM antibodies may be present several years after recovery from tularemia. The possible role of antibodies in host defense to *F. tularensis* is largely unknown.

A cell-mediated immune response also develops during tularemia, as demonstrated by the delayed-hypersensitivity test or by the *in vitro* stimulation of T cells. An immunospecific response can usually be demonstrated within 2 weeks of onset of disease, and thereafter during more than two decades. Similar to other intracellular parasites, cell-mediated immunity toward *F. tularensis* is a prerequisite of host protection.

Evasive strategies by the organism

F. tularensis possesses an abundant capsule, which affords complete protection against complement-

induced lysis and gives resistance to intracellular killing by polymorphonuclear leukocytes. This resistance is a virulence trait, which is lost in the attenuated live vaccine strain *F. tularensis* LVS. LVS is efficiently killed by polymorphonuclear leukocytes due to strictly oxygen-dependent mechanisms. Both a wild strain of *F. tularensis* and LVS induce a respiratory burst in the phagocytes during endocytosis, but only LVS is susceptible to the hypochloric acid and hydrogen peroxide produced as a result of the burst. The actual virulence factor has not been identified.

There is no evidence to indicate that potent toxins are produced by *F. tularensis*. Similar to other facultative intracellular bacteria, *F. tularensis* seems to cause disease by a rapid proliferation in mononuclear phagocytes. A fulminating disease is prevented by evoking an effective T cell-mediated immune response before the bacterial burden becomes too large.

Vaccines

Host protection against tularemia is induced by natural infection or by vaccination with viable attenuated bacteria but not by vaccination with killed bacteria. Live tularemia vaccines were developed in the USSR during the Second World War. In 1956, a mixture of attenuated type B strains of *F. tularensis* was transferred from the Gamaleya Institute in Moscow to Fort Detrick, Maryland. A strain of suitable virulence was isolated, tested for safety and efficacy in humans and introduced as the live vaccine strain *F. tularensis* LVS. According to a retrospective study on the occurrence of laboratory-acquired type A tulare-

mia at Fort Detrick, LVS affords effective protection against respiratory tularemia and modifies signs and symptoms of the ulceroglandular form of the disease. Thus, an attenuated vaccine strain originating from *F. tularensis* type B affords protection against virulent type A organisms, indicating that the two biovars share determinants important to induce T cell-mediated immunity.

FUNGI, IMMUNITY TO

Thomas S Harrison and **Stuart M Levitz**, The Evans Memorial Department of Clinical Research and the Department of Medicine, Boston University School of Medicine, Boston, Massachusetts, USA

The fungi are nonmotile eukaryotes that possess a cell wall and reproduce by means of spores. Over 100 000 species of fungi have been described, but only 100–200 regularly cause disease in humans. Most fungi are saprophytes rather than obligate parasites, human infection being an incidental event in the life cycle of those organisms capable of growing at body temperature in the environment provided by human tissues. However, there are many exceptions to this generalization: *Candida albicans*

colonizes mucocutaneous and gastrointestinal surfaces and is a part of the normal human flora; the dermatophytes are a group of specialized fungi causing localized infections of skin, nails and hair by virtue of their ability to utilize keratin; and the dimorphic fungi grow as saprophytic molds in soil or vegetation but can transform at 37 °C into parasitic yeast forms well-adapted for survival in susceptible mammalian hosts. In addition to causing localized and systemic infections, fungi can trigger immune-

mediated hypersensitivity reactions that can present as asthma, extrinsic allergic alveolitis, or allergic bronchopulmonary aspergillosis.

The medically important fungi are a very diverse group providing a formidable challenge to the immune system. Moreover, even within species, variations in morphology with associated changes in surface antigens are common and not confined to the dimorphic fungi. For example, in susceptible hosts, inhaled *Aspergillus* conidia shed waxy surface coats, swell and exhibit new surface antigens, then germinate to form hyphal filaments with further distinct antigens. These surface changes evoke distinct host humoral and cellular responses. Within tissues, *C. albicans* may grow as yeast-like blastoconidia, pseudohyphae and hyphae that differ in surface antigen expression. Moreover, *C. albicans* and other fungi can undergo heritable high-frequency switching of surface antigenic phenotypes *in vivo*.

A broad array of host defense mechanisms have evolved to protect humans against fungal invasion. Even the most pathogenic of the dimorphic species, *Coccidioides immitis* and *Histoplasma capsulatum*, usually induce only asymptomatic or self-limited infections in persons with intact host defenses. The majority of serious fungal infections occur in persons with defects in one or more of these defenses. Awareness of the type of compromise afflicting a host enables the clinician to predict which mycoses are likely to occur (Table 1). Conversely, a patient not known to be immunocompromised who presents

with a disseminated fungal infection usually warrants investigation for an underlying immunodeficiency. Cell-mediated immunity appears to be especially important for host defense against *Cryptococcus neoformans*, and the endemic dimorphic fungi, *C. immitis*, *H. capsulatum*, *Blastomyces dermatitidis* and *Paracoccidioides brasiliensis*. Protection against *Pneumocystis carinii*, which has been recently classified as a fungus, is also dependent upon intact cell-mediated immunity. Protection against invasive candidiasis, aspergillosis and mucormycosis is more dependent on intact neutrophil function.

Non-specific immunity

A number of nonspecific host factors form an important first line of defense against fungal invasion. These include the mechanical barrier provided by the skin and mucous membranes, competition for nutrients from the normal indigenous bacterial flora, and the mucociliary clearance system of the respiratory tract. The importance of these factors is illustrated by the association of disseminated candidiasis with the disruption of mechanical barriers by burns, surgical wounds or intravenous catheters and with the inhibition of normal bacterial flora by broad-spectrum antibiotics. In serum, chelation of iron and other essential heavy metals restricts the growth of many fungi. The association of mucormycosis with therapy with the iron-chelator deferoxamine is thought to be due to the ability of the causative

Table 1 Etiological agents of systemic fungal infections associated with specific predisposing factors

Predisposing factor	Etiological agent(s)
Traumatized skin and mucosal surfaces	<i>Candida</i> species
Ketoacidosis	Agents of mucormycosis
Deferoxamine therapy	Agents of mucormycosis
Neutropenia	<i>Candida</i> species (disseminated disease) <i>Aspergillus</i> species Agents of mucormycosis <i>Pseudoallescheria boydii</i> <i>Trichosporon</i> species <i>Fusarium</i> species
Chronic granulomatous disease	<i>Aspergillus</i> species <i>Candida albicans</i> (disseminated disease)
Impaired cell-mediated immunity	<i>Candida</i> species (mucocutaneous disease) <i>Cryptococcus neoformans</i> <i>Histoplasma capsulatum</i> <i>Coccidioides immitis</i> <i>Paracoccidioides brasiliensis</i> <i>Blastomyces dermatitidis</i> <i>Penicillium marneffei</i> <i>Pneumocystis carinii</i>

fungi to use iron-saturated deferoxamine as a siderophore. Similarly, ketoacidosis may predispose patients to mucormycosis by making iron more readily available to the fungus. In addition, incompletely characterized serum factors, distinct from complement, have been reported to inhibit the growth of *Cryptococcus neoformans*, *C. albicans* and *Rhizopus oryzae*.

Complement

Unlike 'serum-sensitive' bacteria and viruses, fungi are resistant to lysis by the terminal components of the complement system, even in the presence of specific antibody. However, complement components are important opsonins facilitating the binding and ingestion of fungi by phagocytic cells. Fungi are generally potent activators of the alternative complement system. C3 fragments have been shown to be deposited on the surface of a number of pathogenic species. For *C. neoformans*, nearly all of the C3 is present as iC3b, while for *A. fumigatus* and *C. albicans*, both C3b and iC3b are present on the fungal surface. Activation of complement by fungi has also been shown to generate the potent chemoattractant C5a, which serves to recruit inflammatory cells to sites of infection.

Neutrophils

Neutrophils are of paramount importance in protection against a number of mycoses. In particular, disseminated candidiasis and invasive aspergillosis are not uncommonly seen in neutropenic patients. *In vitro*, neutrophils can kill the hyphae of *C. albicans* and *A. fumigatus*. Hyphae of both fungi stimulate neutrophils to undergo a respiratory burst and degranulate. The oxidants generated (e.g. hydrogen peroxide and hypochlorous acid) and granule products released (e.g. defensins) are fungicidal. The importance of neutrophils in defense against *C. albicans*, *A. fumigatus*, and other catalase-positive fungi is also shown by the frequency of these mycoses (20% in one large series) in patients with chronic granulomatous disease (CGD). Neutrophils from these patients are defective in their ability to generate microbicidal oxidants and are unable to kill *A. fumigatus* hyphae. *In vivo* administration of recombinant interferon γ (IFN γ) to CGD patients has been shown to significantly reduce the incidence of serious infections. Neutrophils from IFN γ -treated CGD patients acquire the capacity to damage *A. fumigatus* hyphae.

Monocytes and resident macrophages

The antifungal activities of monocytes and resident

macrophages have been extensively studied. Macrophages from different species and different anatomic sites vary in their capacity to inhibit and kill fungi. For example, activated murine peritoneal macrophages have potent antifungal effects on *C. neoformans*. However, investigators have been mostly unsuccessful demonstrating antifungal activity of activated human macrophages. The L-arginine-dependent generation of nitric oxide by activated murine macrophages appears to be at least partly responsible for antifungal effects. Generation of microbicidal concentrations of nitric oxide has been difficult to demonstrate in human macrophages, which may help to explain why antifungal effects seen in mouse macrophages have not always been reproduced in human cells.

For most fungi that cause systemic disease, initial exposure occurs by inhalation of airborne spores or yeast cells. Bronchoalveolar macrophages are thought to constitute a particularly important component of the immune response to these fungi. In several studies bronchoalveolar macrophages have been found to have greater antifungal activity than, for example, peritoneal macrophages. *In vitro*, bronchoalveolar macrophages can kill the spores but not the hyphae of *A. fumigatus*. Neutrophils, on the other hand, cannot kill ungerminated spores but can kill hyphae. *In vivo*, two lines of phagocyte defense may combine to prevent the establishment of infection. Spores that are not killed by resident bronchoalveolar macrophages will be susceptible to attack by recruited neutrophils. Bronchoalveolar macrophages have also been shown to prevent the phase transition of *B. dermatitidis* conidia (the inhaled form) into invasive yeasts, illustrating another mechanism whereby the establishment of infection may be prevented. Recently, some progress has been made in identifying the ligands and receptors involved in the binding of fungi by macrophages (Table 2, Figure 1).

Natural killer cells

Natural killer (NK) cells have been shown to inhibit the growth of *C. neoformans* and *P. brasiliensis* *in vitro*. In some, but not all, murine models of cryptococcosis, NK cells were also found to contribute to clearance of the organism. However, in mice infected with *H. capsulatum*, no significant role for NK cells in host defense could be demonstrated. Recently, human T lymphocytes have been shown to bind to and inhibit the growth of *C. neoformans* and *C. albicans* *in vitro*. The role *in vivo* of this direct antifungal activity of nonspecific T cells has yet to be determined.

Table 2 Examples of receptors and ligands involved in the binding of pathogenic fungi to macrophages

Pathogen	Ligand(s)	Receptor(s)
<i>H. capsulatum</i>	Unknown	CD18 (β chain of CR3, ^a CR4, and LFA-1)
<i>B. dermatitidis</i>	WI-1, a cell wall protein	CR3 and CD14
<i>C. neoformans</i>	Deposited iC3b ^b	CR1, CR3, CR4
<i>C. albicans</i>	Cell wall mannoproteins and β -glucans	Mannose and β -glucan receptors
<i>A. fumigatus</i>	Conidial cell wall polysaccharides	Mannose and/or β -glucan receptors

^aCR, complement receptor.

^bRecognition of *C. neoformans* by macrophages generally requires complement activation. Binding of opsonized organisms via complement and Fc receptors is an additional mechanism common to many other fungi.

Figure 1 Scanning electron micrograph of a human monocyte-derived macrophage binding and ingesting serum-opsonized *Cryptococcus neoformans*. Micrograph by Robert Liss (with permission) from material prepared by Stuart Levitz and Abdul Tabuni.

Specific immunity

Antibody

Although it is difficult to draw definite conclusions, for most of the mycoses there is little evidence to suggest that specific antibodies are critical to host defense. In marked contrast to patients with impaired cell-mediated immunity, those with hypogammaglobulinemia are not particularly predisposed to the development of invasive fungal infections. The principal role of antibody may be to enhance binding of fungi to phagocytic cells via Fc receptors. In the case of cryptococcosis, specific antibody enhances the activity of most effector cell populations in *in vitro* systems and passive administration of antibody has been shown to be beneficial in animal models of infection. Some evidence from mouse models also suggests a role for humoral immunity in resistance to systemic candidiasis. Specific antibodies are also important in the pathogenesis of allergic responses to inhaled fungi. For example, IgE-mediated immediate hypersensitivity reactions to fungal allergens may play a part in some asthmatic attacks and precipitat-

ing antibodies to fungal antigens are responsible for some of the manifestations of extrinsic allergic alveolitis through the formation of immune complexes.

Specific cell-mediated immunity

Specific cell-mediated immunity is critical for a protective immune response to *C. neoformans* and the dimorphic fungi, and is involved in protection against dermatophyte infections. Cell-mediated immunity, rather than intact neutrophil function, is also of primary importance for protection against mucocutaneous candidiasis. These mycoses are seen with increased frequency in patients with the acquired immune deficiency syndrome (AIDS), lymphomas, sarcoidosis, and in those taking immunosuppressive medications such as corticosteroids, cyclophosphamide, or azathioprine. The high incidence of fungal infections in human immunodeficiency virus (HIV)-infected patients is particularly striking. HIV infects CD4⁺ lymphocytes and macrophages, the two cell types whose interactions are central to the cell-mediated immune response.

Development of a specific cell-mediated immune response to these fungi is thought to require antigen-presenting cells (generally mononuclear phagocytes), to process and present fungal antigen(s) to T lymphocytes (generally CD4⁺ helper cells). CD4⁺ lymphocytes expressing antigen-specific receptors recognize antigen in association with major histocompatibility complex (MHC) class II molecules, proliferate and release cytokines (e.g. IFN γ and IL-2) that activate effector cells to inhibit or kill the fungus. Studies of mouse models of candidiasis and histoplasmosis suggest that protection may be associated with a T_H1 type response stimulated by the production of IL-12 by antigen-presenting cells and characterized by high levels of IFN γ and IL-2, and low levels of IL-4, IL-5, and IL-10. In addition to CD4⁺ T cells, CD8⁺ T cells may be involved in the immune response to some fungi. In mice infected intratracheally with *C. neoformans*, CD8⁺ cells contribute to clearance of the organism. CD8⁺ T cells

have also been shown to be involved in the generation and expression of delayed-type hypersensitivity to *C. neoformans* in mice.

Activated macrophages are important effector cells, but cytokines generated in the course of a specific cell-mediated immune response may also enhance the antifungal activity of natural killer cells, nonspecific T lymphocytes and neutrophils. Enhanced activity against *C. albicans*, *B. dermatitidis*, *C. neoformans*, *H. capsulatum* and *C. immitis* has been demonstrated following incubation of murine macrophages with IFN γ . Interleukin 2 activates murine lymph node cells and human peripheral blood lymphocytes to kill *C. albicans* and *C. neoformans*, respectively. Other cytokines, including tumor necrosis factor, granulocyte-macrophage colony-stimulating factor (GM-CSF) and IL-12, which may be produced during the course of a cell-mediated immune response, also have been reported to activate effector cells to inhibit or kill fungal targets. Cytokines that have suppressive effects, including IL-10 and transforming growth factor β , may also be generated in response to fungal challenge. When produced in appropriate amounts, these cytokines may be important in limiting damage to host tissues. Nevertheless, many of the clinical manifestations of the mycoses result from the inflammatory response to fungal antigens. Mediastinal fibrosis, a rare complication of infection with *H. capsulatum* thought to result from an overexuberant cell-mediated immune response, is an extreme example.

Vaccination and immunotherapy

The development of vaccines against the important systemic fungal infections is under intense investigation. A vaccine consisting of formaldehyde-killed spherules of *C. immitis* was protective in a mouse model of coccidioidomycosis, but no efficacy was demonstrated in a large trial of susceptible persons in the endemic area. Local reactions limited the dose that could be given. Immunization with subcellular fractions or purified antigens is likely to be better tolerated and suitable antigens are under development for both *C. immitis* and *H. capsulatum*. Cryptococcal glucuronoxylomannan, the major component of the polysaccharide capsule of *C. neoformans*, has been linked to tetanus toxoid and used to immunize mice. Conjugation with tetanus toxoid enhanced immunogenicity and conferred T cell-dependent properties to glucuronoxylomannan.

Most serious fungal infections, however, occur in significantly immunocompromised patients who are likely to have a suboptimal response to immunization and/or a suboptimal response to infection

despite prior immunization. It will need to be shown for each patient group and each antigen that active immunization can confer protection in these circumstances.

The defects in host immunity associated with serious fungal infections are being defined and some progress has been made in attempts to boost or reconstitute the immune response. Examples include IFN γ in patients with chronic granulomatous disease and granulocyte colony-stimulating factor and GM-CSF in neutropenic patients. In the case of cryptococcosis, monoclonal antibodies to capsular glucuronoxylomannan have been shown to confer protection when passively administered to mice infected with *C. neoformans*. This, despite the fact that specific antibodies appear to play a limited role in normal host defense against *C. neoformans*. Increased understanding of the complex network of cytokines regulating the cellular immune response has raised additional therapeutic possibilities. Soluble IL-4 receptor and antibody against IL-10 have been shown to be beneficial in murine candidiasis and IL-12 has been shown to be beneficial in animals models of cryptococcosis and histoplasmosis. Nevertheless, current treatment for serious fungal infections depends largely on antifungal drugs. Much additional experimental and clinical work is needed to define the role of adjunctive immunotherapy.

FUSOBACTERIUM, INFECTION AND IMMUNITY

Itzhak Brook, Department of Pediatrics, Georgetown University, Washington DC, USA

Fusobacterium spp. are gram-negative, nonsporulating, nonmotile and, generally, moderately long filamentous organisms, sometimes slightly elongated spindle-shaped rods, that belong to the family Bacteroidaceae. They are weak fermenters or unable to ferment sugar. The ability of *Fusobacterium* spp. to produce *N*-butyric acid without isobutyric or isovaleric acids differentiates them from the other Bacteroidaceae. There are currently 12 known species of *Fusobacterium*. The species seen most often in clinical infections include *F. nucleatum* (currently divided into four subspecies), *F. necrophorum*, *F. gonidiaformans*, *F. naviforme*, *F. mortiferum*, *F. necrogenes*, *F. ulcerans*, *F. russii* and *F. varium*. Of these, *F. nucleatum* is best able to produce the enzyme β -lactamase.

Fusobacterium spp. are part of the normal oral, gastrointestinal and female genital tract flora; these sites, therefore, are the most common origin of infections that involve these organisms. The organisms are often recovered mixed with other anaerobes and aerobes in polymicrobial infections that are often synergistic.

Fusobacterium spp. produce lipopolysaccharide, endotoxin, neutrophil-cytotoxic substances and DNAase, which have all been associated with virulence. *F. nucleatum* can adhere to lymphocytes and facilitate their activity. The adherence is believed to be mediated by lecithin-like ligands. It can be inhibited by *N*-acetylglactosamine, lactose and α - and β -methylgalactoside. *F. nucleatum* also has an immunosuppressive effect on human peripheral blood lymphocytes. Such an effect may enhance the pathogenicity of the organisms as well as other copathogens.

As with other anaerobic bacteria, the ability of *Fusobacterium* spp. to induce subcutaneous abscesses correlates with the presence of a mucopolysaccharide layer in the cell wall. The ability to produce subcutaneous abscesses in experimental animals could, therefore, be an indication of the organism's virulence, as has been noticed with other anaerobic strains.

Factors associated with infections involving *Fusobacterium* spp. include break-up of the normal cutaneous and mucosal defenses, as may occur in Epstein-Barr virus pharyngitis, tissue injury caused by surgery or trauma, and impaired blood supply caused by microvascular disease. Moreover, the production of proteolytic enzymes by *Fusobacterium* spp. may allow early invasion of regional veins, even without tissue necrosis. Furthermore, the low oxidation-reduction potential and oxygen-free environment of devitalized tissue allows growth of these organisms.

Support for the pathogenic role of *Fusobacterium* spp. may be derived from *in vivo* studies that have demonstrated their synergistic potential with other anaerobic and aerobic bacteria. With few exceptions, the presence of *Fusobacterium* spp. enhanced the growth of other aerobic and anaerobic bacteria. Bacterial synergy was demonstrated between *Fusobacterium* spp. and anaerobic cocci, *Staphylococcus aureus* and *Pseudomonas aeruginosa* by means of a subcutaneous abscess model in mice. In this model, *Fusobacterium* spp. enhanced the formation of abscesses and mortality when inoculated with the other organisms.

The spectrum of infections in which *Fusobacterium* spp. play a pathogenic role include bacteremia, head and neck infections (such as chronic otitis media, sinusitis and mastoiditis, peritonsillar and retropharyngeal abscesses, Vincent's angina, gingival and dental infections), pulmonary infections (aspiration pneumonia, lung abscesses and empyema), intracranial infections (meningitis and intracranial abscesses), gastrointestinal infections (peritonitis, hepatic and abdominal abscesses), osteomyelitis, urogenital (prostatic and female genital abscesses, amnionitis) as well as skin and soft tissue infections, especially around the oropharyngeal area.

Fusobacterium spp. have been associated with single or polymicrobial bacteremia, of primarily oropharyngeal origin, that may accompany cervical

septic thrombophlebitis, necrotizing pneumonia or metastatic infection, known as Lemierre's disease.

F. nucleatum (currently divided into four subspecies) is the predominant fusobacterium found in the oral flora and in human infections. It has been associated with dental plaques, necrotizing gingivitis, acute ulcerative gingivitis (Vincent's angina) and periodontitis. It is also the major fusobacterium recovered from all head and neck infections and their sequelae.

F. nucleatum and related species can be recovered in a variety of mixed infection in animals, including bovine pyometra, necrobacillosis of the jaw in macropods and feline abscesses following cat bites.

Elevated antibodies to protein antigens of *F. nucleatum* were found in patients with periodontal disease, peritonsillar cellulitis and abscesses, infectious mononucleosis and acute streptococcal, nonstreptococcal and recurrent tonsillitis. It is possible that the increase in antibodies to these outer membrane proteins – which may contribute to bacterial attachment – may signify a potential direct or indirect pathogenic role for this organism in these infections.

F. necrophorum (currently divided into two subspecies) is the second most common pathogen in humans. It is found in pharyngeal and tonsillar infection associated with bacteremia, otitis, pneumonia, liver and colonic infections. It has a variety of virulence factors that makes it a potentially greater pathogen than other fusobacteria. These include a leucocidin, hemolysin, a hemagglutinin, a lipase, a DNAase, a proteinase and a lipopolysaccharide endotoxin.

F. necrophorum (divided into two biovars, A and B) is part of the normal gastrointestinal flora of herbivores and other species, and can cause endogenous infection in these hosts as well as in humans. Necrobiosis in humans (generally due to biovar B) is a throat infection followed by systemic spread and metastatic abscesses. Necrobacillosis infections in animals (generally due to biovar A) are usually polymicrobial and include coagulative necrosis and abscesses and can cause mortality. Necrobacillosis generally occurs in the oral cavity, liver and foot. Bovine hepatic necrosis is hematogenous, originating from minimal lesions and foot rot. Necrobacillosis can affect wild and domestic animals.

Necrobacillosis is often a synergistic infection. *In*

vivo synergy between *F. necrophorum* and *Actinomyces pyogenes*, *Escherichia coli* and *Staph. aureus* was demonstrated in mice, and growth stimulation between *F. necrophorum* and *A. pyogenes* was found *in vitro*.

Delayed-type hypersensitivity to *F. necrophorum* could be induced in mice, and leukotoxin-specific antibodies can be detected in cattle with induced or naturally-acquired hepatic abscess due to this organism. Antibodies to *F. necrophorum* can be detected after infection using passive hemagglutination and enzyme-linked immunosorbent assays. However, protection against reinfection is not always achieved after natural infection or vaccination with a toxoid prepared from the cytoplasmic fraction of *F. necrophorum*. Even utilization of an extreme method of immunization, by producing a severe subcutaneous *F. necrophorum* infection followed by curative therapy with metronidazole, produced only slight protection. That *F. necrophorum* is naturally a weak immunogenic pathogen is therefore plausible.

G

GAMMAGLOBULIN

Charlotte Cunningham-Rundles, Department of Medicine and Pediatrics, Mount Sinai Medical Center, New York, NY, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Gammaglobulin is a somewhat ambiguous term that still remains in common usage despite attempts to substitute 'immunoglobulin' in its place. In general terms, 'gammaglobulin' is a class of plasma proteins composed almost entirely of immunoglobulins (Igs), the proteins that function as antibodies. These plasma proteins are characterized by a very slow electrophoretic mobility in an alkaline buffer (Figure 1). 'Gammaglobulin' is also used as a clinical name, given to the immunoglobulin concentrates that are given parenterally to humans for immunoprophylaxis against infectious disease, or for passive antibody replacement in humoral immunodeficiency disease.

The term 'gammaglobulin' has deep roots in the history of immunology and the evolution of immunoprophylaxis. The globulins were those proteins found to be soluble in dilute salt solution and precipitated at half saturation with ammonium sulfate, in distinction from the albumins, which require complete saturation with ammonium sulfate in order to precipitate them. Typical globulins were first believed to be insoluble in water in the absence of salt, but the globulins were later divided into two

parts, the 'euglobulins' (mostly IgM) of which this feature is true, and the 'pseudoglobulins' (mostly IgG) which dissolve even in the absence of salt.

The electrophoretic separation of plasma into components of various charge, including the α , β and γ fractions, was first performed by Tiselius, who gave these names to the fractions in 1937. Two years later, Tiselius and Kabat identified antibody in the slowest moving proteins, the γ fraction. Ethanol precipitation of the gammaglobulin proteins from pooled human serum, introduced in 1944 by Cohn and colleagues, became a standard method of isolating almost pure gammaglobulin (called fraction II). Figure 2 shows the plasma fraction scheme that was developed. After fraction II was found to contain most of the antibodies present in serum, it became an important prophylactic agent given parenterally to humans to protect against certain infectious diseases. Later, this immunoglobulin concentrate was introduced as a means of reconstitution for immunodeficient patients who had no antibody production of their own.

Numerous physical and chemical studies on the properties of the gammaglobulin molecules were

Figure 1 Serum protein electrophoresis. Typical conditions for separation on paper or other suitable support include a 0.1 M sodium diethylbarbital buffer (pH 8.6, potential gradient 6 V cm⁻¹) over a time period of 250 min.

Figure 2 Cohn–Oncley alcohol fractionation. Plasma fractionation procedures yield a gammaglobulin concentrate (fraction II).

undertaken between 1948 and 1955 following the discovery that myeloma proteins were immunoglobulin molecules. IgG and IgM were described first, followed by IgA (1960), IgD (1965) and IgE (1966). In 1964, following the discovery that animal IgG protein could be subdivided, it was found that human IgG was composed of four classes: IgG1, IgG2, IgG3 and IgG4.

Gammaglobulin preparations

Commercial preparations of gammaglobulin, usually obtained from pooled plasma from 500–2000 or more donors by the Cohn–Oncley process, contains approximately 85% IgG, 10% IgM, 5% IgA and traces of other plasma proteins. The immunoglobulin concentrates contain the majority of antibodies of the IgG class present in the starting plasma. Two main forms of these immunoglobulin concentrates are available: a 15% solution intended for intramuscular (or subcutaneous) use, and lyophilized powders or liquids intended for intravenous use. The former often contains $8\text{--}20\ \mu\text{g ml}^{-1}$ thiomersal, as the solution is packaged in multidose vials; it also contains immunoglobulin aggregates which make it unacceptable for intravenous use. The lyophilized powders

and liquids for intravenous use contain no preservatives.

Intravenous infusion of gammaglobulin concentrates (initially the fraction II of the Cohn–Oncley process) was first attempted in the 1950s. Unfortunately, these infusions resulted in severe reactions in a number of instances, probably because of complement activation due to the infusion of aggregates. However, over time, various methods of modifying the immunoglobulin solutions were devised to produce products suitable for intravenous use. These methods included: enzymatic treatment of immunoglobulin; addition of chemical groups to prevent aggregation; reduction, sulfonation, or reduction followed by alkylation; addition of stabilizers (maltose, sucrose, albumin, glycine, mannitol); ion exchange column filtration; and precipitation of aggregates by polyethylene glycol.

The best method of preparation of intravenous immunoglobulin has not been established, and no comparative trials have been performed to compare the types available. Any method that produces an immunoglobulin concentrate containing intact and unmodified immunoglobulin in a form suitable for intravenous administration might be potentially satisfactory. Since enzyme-treated or reduced and

alkylated immunoglobulin has reduced effector functions in terms of opsonic capacity or fixation of complement, these preparative methods are no longer favored. There is also a general consensus that these concentrates should contain IgG subclasses in the approximate proportions present in normal plasma and that no preservatives be added.

Gammaglobulin for prophylaxis and disease prevention

The use of intramuscular gammaglobulin as a prophylaxis against infectious disease in persons exposed to hepatitis A has established therapeutic benefit. Intramuscular immunoglobulin is also recommended for nonimmune women exposed to rubella in early pregnancy, and for infants or immunosuppressed persons exposed to measles. Specific high-titered preparations of gammaglobulin are also available for prevention of disease following exposure to chicken pox (for immunosuppressed individuals) or following suspected inoculation with rabies virus or tetanus organisms.

Gammaglobulin has also been used for antibody replacement in patients with congenital immunodeficiency diseases such as X-linked agammaglobulinemia (Bruton type), common variable immunodeficiency, and other antibody deficiency syndromes in which B cells do not secrete adequate amounts of immunoglobulin. Intramuscular immunoglobulin replacement therapy was introduced in 1952; the generally recommended dose was $25 \text{ mg kg}^{-1} \text{ week}^{-1}$, usually given at biweekly intervals.

In the last decade the use of intravenous immunoglobulin has largely replaced the use of intramuscular immunoglobulin for treatment of immunodeficiency diseases, as the amount of immunoglobulin which can be easily administered is much greater when delivered by the intravenous route. Additionally, studies have shown that patients with primary immunodeficiency disease benefit from the larger doses, and that the serum levels of IgG can be normalized. The dosage range for intravenous immunoglobulin in antibody deficiency is generally $200\text{--}400 \text{ mg kg}^{-1}$ given at 2–4 week intervals.

Safety of gammaglobulin

A major concern surrounding the infusion of blood and blood products is the potential for the transmission of viruses. Although there was previously a risk of infection with hepatitis C for patients who

received factor VIII and factor IX concentrates, human immunoglobulin concentrates have not historically been noted for the transmission of hepatitis. However, there have been a few cases of hepatitis on record that were traceable to injections of intramuscular immunoglobulins, and there have also been instances of outbreaks of hepatitis C in patients who received intravenous immunoglobulins. Most recently, intravenous immunoglobulin concentrates of one manufacturer produced hepatitis C in more than 100 patients in the USA in 1993–1994, with a number of affected individuals also being reported in other countries. Since in each case the starting immunoglobulin is the same as for intramuscular immunoglobulin, it has remained a mystery how intravenous immunoglobulin could acquire infectivity during manufacturing. Various viral inactivation steps have now been incorporated into the processing of most immunoglobulin concentrates, with no cases of hepatitis being reported when such procedures have been employed.

Also of concern has been the theoretical possibility that immunoglobulin concentrates could transmit the human immunodeficiency virus (HIV) virus; however, there have been no documented cases of HIV transmission via any immunoglobulin concentrates. Thus it appears unlikely that immunoglobulin concentrates have any potential for transmitting this virus. Purposeful contamination of plasma with the virus and subsequent testing of residual infectivity at various points along the preparation cycle shows that several steps in the scheme remove infectivity.

GASTROINTESTINAL TRACT INFECTIONS

Herman Friedman, Department of Medical Microbiology and Immunology, University of South Florida College of Medicine, Tampa, Florida, USA
Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Gastrointestinal (GI) infectious diseases are widespread in developing areas of the world and are also a disturbing problem in industrial regions, despite greater emphasis on sanitary measures to provide safe food handling and water distribution. Diarrheal disease is the most common acute infectious disease in the world and responsible for considerable mortality in developing countries. Microorganisms associated with human GI infections include various species of bacteria, fungi, viruses and protozoa. Helminths also cause diarrheal disease after infecting the GI tract. The acquisition of diarrheal diseases depends upon both broad and specific aspects of the characteristics of individuals and on their socioeconomic environment and activities. Age is a determining factor for susceptibility to infection by some of these organisms. For some enteric pathogens, very young individuals are particularly at risk. For other pathogens the elderly are most at risk and for others both age groups are readily affected. However, regardless of age, severe immunocompromised patients, including those with the acquired immune deficiency syndrome (AIDS), are particularly susceptible to secondary infections, including diarrheal disease. As might be expected, pathogenic mechanisms that affect the intestine and result in diarrhea vary with the organism or group of organisms.

The normal intestinal flora consists of a wide variety of distinctive species of microorganisms that coexist in a complex ecosystem specifically adapted to the environmental conditions found in the GI tract. This flora maintains a symbiotic relationship with the host, is remarkably stable and can play a competitive role in preventing colonization of the GI tract by invading pathogens. In order to colonize the GI tract and cause infections, pathogens must be able to overcome or circumvent defense mechanisms of the host. The most important in this regard is integrity of the mucosal epithelium. Once the flora can penetrate broken mucosal epithelium, even some normally nonpathogenic flora can reach the deep tissues and disseminate through the bloodstream to other organs. The acidity of the stomach represents a significant deterrent. Other nonspecific host defense factors include the relative rapid motility of the normal gut which acts to deter bacterial colonization by removal of microorganisms. Expulsion of the microorganism by peristalsis is aided by the mucosal layer

which also serves as a diffusion barrier, limiting bacterial attachment to the mucosal surface. Specific as well as nonspecific mucosal immunity is a major area of interest to both microbiologists and immunologists, and appears to play a major role in preventing infection. For example, secretion of specific secretory immunoglobulin A (IgA) antibody is important in preventing adherence of microorganisms and replication of the invading pathogen at the mucosal level.

Bacterial infections

Mechanisms that affect the intestine and result in diarrhea vary with the bacteria involved. Diarrhea usually occurs in individuals harboring bacteria that produce toxins or other products capable of affecting intestinal epithelial cells directly and thereby alter their secretory function. Watery, noninflammatory diarrhea occurs with cholera and rotoviral disease. *Clostridium difficile* and enterotoxigenic *Escherichia coli* infections, among others. Disease caused by microorganisms such as *Shigella*, *Salmonella enteritidis*, and enteroinvasive *E. coli* usually involve the effects of exotoxins produced by the microorganism which affect the epithelium, resulting in inflammatory diarrheal disease. However, some gastrointestinal pathogens penetrate more deeply into tissues than others.

It is widely acknowledged that GI infection with various bacterial pathogens may be serious. Many are capable of overcoming protective host factors, although some bacteria that cause disease in the intestine are considered normal flora, but some strains acquire virulence determinants that mediate diarrheal disease. For example, enterotoxic strains of *E. coli* colonize the small intestine through attachment structures such as fimbriae or pili and elaborate thermolabile and thermostable toxins. These can result in net fluid and electrolyte secretion into the lumen of the small intestine. Also, enteroinvasive *E. coli* strains invade and proliferate within epithelial cells of the colon and cause a dysentery-like disease similar to that produced by *Shigella*, the classic agent of bacillary dysentery. Dysentery caused by this organism is a major health problem among infants worldwide. *Escherichia coli* strains that do not invade colonic epithelial cells can cause a hemorrhagic colitis, which is now considered an important health problem in institutions, including

nursing homes, daycare centers, schools, etc. Such enteropathogenic *E. coli* are also important causes of infant diarrhea in developing countries. These organisms colonize the ileum rather than the colon, are noninvasive, and associated with a distinctive histopathology of the microvillus membrane. Knowledge regarding the pathogenesis of some enteric diseases caused by microorganisms has within the last decade advanced markedly at both the cellular and molecular levels. For example, the mode of action of toxins, virulence factors such as adhesions, nutritional requirements of the invading microorganism, the mechanism of invasion, effects on eukaryotic cell signaling and stimulation of the inflammatory response by induction and actions of cytokines are now known in some depth and shown to be important factors.

The host response to cholera and cholera toxins has provided a model for studying similar aspects of molecular pathogenesis of other bacterial enteric diseases. It is now known there are virulence factors for *V. cholera* that enable colonization of the intestine and some molecular aspects of genetic control of these factors are now understood. The *E. coli* strains associated with diarrheal disease, including those which are enterotoxigenic and enteropathogenic, cause pathogenic responses similar to cholera but in a less severe form. It is known that cholera toxin enhances intracellular adenylate cyclase activity while *E. coli* enterotoxin increases guanylate cyclase activities. Nevertheless, in both cases the net result is increased secretion of water electrolytes but the electrolyte affected differs as well as the extent of the responses induced. Furthermore, enterotoxigenic *E. coli* toxins are cytokines that directly affect intestinal epithelial cells. The result is an inflammatory diarrhea rather than a watery noninflammatory one. In this pathogenesis the disease resembles shigellosis rather than cholera. Other *E. coli* strains produce hemorrhagic diarrhea. Thus it is obvious that within this one species various mechanisms of action on the human gastrointestinal tract have developed. It is important to note, however, that most strains of *E. coli* are not pathogenic and many are members of the human indigenous intestinal microflora and can participate in protecting the host from infection by a typical pathogen. Genetic control of the various virulence factors in different strains of one bacterial species or among groups of species may be plasmid or chromosomal in origin, or both.

Other invasive enteropathogens that have been studied in terms of their ability to cause diarrhea include *Yersinia* and *Campylobacter*. *Campylobacter* is recognized as an important and common cause of GI infection and a species of this bacterium, now

known as *Helicobacter pylori*, but first classified in the *Campylobacter* genus, is now known to be an important cause of gastritis and peptic ulcers.

Viral infections

Viruses are also known to cause GI infections, including diarrhea. Among the most important viral agents are the rotoviruses, as well as the Norwalk agent. Such viruses infect small intestinal enterocytes at the villi. Villus cells absorb electrolytes and their destruction leads to net secretion of fluid into the lumen. Rotoviruses are known to be a major cause of epidemic diarrhea in infants and young children. The Norwalk agent is responsible for epidemic outbreaks among schoolchildren and adults. Despite controversies about mechanisms of immunity against viral gastroenteritis, effective rotovirus vaccines based on serospecific immune protection against the disease are being developed. Combined polyvalent vaccines, as well as genetic constructs containing epitopes of major human rotovirus serotypes, are currently being evaluated as protective immunogens in field trials.

Parasitic infections

Various gastrointestinal parasites, including protozoa such as *Giardia lamblia*, *Entamoeba histolytica* and *Cryptosporidium* spp., are important causes of gastrointestinal diseases. *Giardia* is known to infect the small intestine of all age groups and produces a mild but annoying diarrhea. The mechanism of infection is quite complex and not well understood, even though this parasite is not invasive. *E. histolytica* is often found in asymptomatic individuals but has the capacity to produce a chronic or dysentery-like diarrhea. This organism can penetrate the intestinal tissue causing ulceration of the intestinal epithelium and may spread to other tissues and organs. Serious infections by *Cryptosporidium* are usually considered rare but these parasites are an important cause of diarrhea and colitis in humans in both developing and developed countries and this parasite is an important disease-causing organism in patients with acquired immunodeficiencies such as AIDS.

Multicellular helminths or worms can colonize the human intestinal tract and often may be important disease-inducing organisms. Among the helminths are the roundworms such as nematodes, the tapeworms, i.e. cestodes, and the trematodes. Many intestinal helminths infect an individual following penetration through the skin or by ingestion. Pathogenesis includes occlusion of the intestinal lumen, tissue invasion, chronic inflammation and mal-

nutrition. Many helminths evade the host immune response by both subtle and complex mechanisms.

Both cellular and humoral immunity develop to protozoa including single cell parasites and amoebas, as well as intestinal helminths. However, such immunity is usually not effective in preventing colonization or disease. IgE responses of the host are thought to be protective and this immunoglobulin class is believed to have possibly evolved mainly in response to intestinal protozoa and helminthic infections.

Vaccine development

Although successful and useful vaccines have not yet been developed except for a few enteric bacteria or viruses, it is expected that by use of molecular techniques to study aspects of active immunization it will be possible to prepare vaccines that are more effective and have fewer side-effects for various human populations. Progress is being made in 1) the development and identification of specific epitopes for protective antigens from bacteria and viruses which cause GI infections, 2) understanding the effective interactions among mucosal, humoral and cellular immune functions which provide GI tract protective barriers, and 3) the development of purified antigenic molecules from several GI tract pathogens, especially bacteria and their exotoxins, modified to eliminate or decrease toxic properties.

GENE CONVERSION

PJ Hastings and Susan M Rosenberg, Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas, USA

There are two main ways by which nucleotide sequences on a DNA molecule can be recombined to give a sequence derived from two different parental sources. They are called gene conversion (conversion) and crossing-over.

A cross-over is a reciprocal exchange such that all sequences on one side of the cross-over are derived from one parental source and all sequences on the other side of the cross-over are derived from the other parental molecule. The other molecule produced from the interaction has the other reciprocal set of information. Thus a cross-over redistributes sequences as if two similar molecules broke at homologous positions and then rejoined, each part of

one molecule with each part of the other. In contrast, conversion is a nonreciprocal transfer of DNA base sequence from one molecule, replacing the homologous sequence on another molecule. Conversion is strongly correlated with crossing-over between markers flanking the site of the conversion, giving rise to the idea that the two represent different consequences of the same recombination event.

Both conversion and crossing-over can occur between homologous sequences on separate DNA molecules, between sister molecules after replication and between homologous sequences on the same molecule (intramolecular events).

Gene conversion serves more than one role in biology. One of its roles is in meiotic recombination and the formation of gametes, whereby conversion is probably involved in the interaction of homologous chromatids that leads to the formation of cross-overs. These cross-overs are visible cytologically as the chiasmata that hold bivalents together on the first meiotic metaphase plate, thus ensuring the orderly separation of homologous chromosomes to opposite spindle poles at anaphase. Conversion events may also be responsible for the initial steps of chromosome synapsis.

A major role of conversion in somatic cells is repair of damage to DNA. In yeast cells, damage to both nucleotide chains (DNA strands) in the same region is repaired by the formation of a double-strand gap which can be filled by copying both strands of a homologous sequence elsewhere in the nucleus. In vertebrate cells also, double-strand breaks are recombinogenic. However, vertebrate cells (and to a lesser extent, yeast cells) have an alternative mechanism for repair of double-strand breaks in DNA via nonsequence-specific end-to-end joining.

A third biological role of conversion is in cell differentiation. This process is best understood at the molecular level in the phenomenon of mating-type switching in yeasts, whereby the genes determining one mating-type are replaced by previously nonexpressed genes of the complementary mating-type by a process of conversion similar to the mechanism of double-strand gap repair. Conversion-like processes in differentiation figure prominently in immunology, both in the ability of some pathogens to change the antigenic properties of their cell surface and in the use of conversion in generation of antibody diversity.

In simpler organisms, there are at least two mechanisms of gene conversion. These are double-strand gap filling, as seen in DNA repair and yeast mating-type switching, and repair of mismatches in heteroduplex DNA, as seen in meiotic conversion. The two following sections describe models that can serve as examples for thinking about these two mechanisms. Most, if not all, recombination events may involve both mechanisms at differing levels of importance.

Formation and correction of heteroduplex DNA

The 1975 model of meiotic recombination of Meselson and Radding may be used to illustrate mechanisms of heteroduplex DNA formation. As shown in Figure 1, the model postulates that the event is initiated by a nick in one nucleotide strand. The 3' end at the nick may then serve as a primer for DNA polymerase (shaded circle labeled 'pol'), which dis-

Figure 1 The Meselson and Radding model for recombination. Arrowed ends represent 3' ends, nonarrowed 5' ends.

places one strand of DNA, forming a loose 5' tail (Figure 1B). Single-strand DNA, and especially single-strand ends, are likely to be recombinogenic because they form a substrate for enzymes that catalyze the invasion and uptake of single-strand DNA into homologous duplex DNA, displacing the like strand from the invaded molecule. The classic example of this activity is that of RecA protein from *Escherichia coli*. Similar activities have now been reported in several prokaryotic and eukaryotic systems. Invasion by the single-stranded tail leads to the formation of a D loop (Figure 1C), in which there is a length of heteroduplex DNA and a loop of the displaced strand. *In vitro*, the length of homology RecA required is only 50 base pairs. Some mis-

matched bases can be accommodated within RecA-promoted heteroduplex.

The Meselson and Radding model postulated that further extension of this length of heteroduplex would occur if the loop were nicked to allow entry of an exonuclease. Concerted action of the polymerase and exonuclease (notched circle labeled 'exo') would allow continued strand displacement and uptake (Figure 1D). The length of heteroduplex formed by this process is described as asymmetric, as it occurs in one chromatid only. The asymmetric extension would cease if the polymerase molecule dropped off the DNA.

The structure shown in Figure 1E is an isomer of that seen in Figure 1D. This isomerization is expected to occur spontaneously and frequently. The structure shown in Figure 1E is known as a Holliday junction. It has the property that it can move by diffusion. More recently, proteins that actively push or branch-migrate such junctions have been shown to assist recombination in bacteria. If such branch-migration is to the right in this diagram, a length of symmetrical heteroduplex is formed (Figure 1F).

If a point of heterozygosity falls into a length of heteroduplex, a mismatched base pair will occur. Most such mismatches will be subject to mismatch repair, which is an excision repair process in which one genotype is excised and replaced by the other to give homoduplex DNA. The change of genotype produced by an invasion to form heteroduplex converts one strand of the duplex. Subsequent mismatch repair, removing the invaded molecule's original sequence, can lead to conversion of both strands.

The Meselson and Radding model postulates that the Holliday junction will be resolved by the action of an endonuclease (cutting at the crossed strands in Figure 1), with a cross-over resulting from resolution of the structure when it is in one isomeric form (Figure 1F) and not when it is in the other (Figure 1G). Holliday junction resolving endonucleases have been found in microbes.

Double-strand break repair

Figure 2 shows an example of a model for recombinational repair of double-strand breaks in DNA. The two interacting molecules, or lengths of homology within molecules, are shown together in Figure 2A. Figure 2B shows the result of processing of the broken ends by polar single-strand exonucleases. The single-strand tails, in this diagram, are presumed to have 3' ends. Both tails may invade the homologous sequence forming two D loops (Figure 2C). The 3' ends may prime DNA synthesis, so that both nucleotide strands of the undamaged molecule are copied

Figure 2 A double-strand-break repair model for recombination. Arrowed ends represent 3' ends, non-arrowed 5' ends.

(Figure 2D). Ligation of the remaining nicks produces a structure with a double Holliday junction (Figure 2E). If it had been the 5' tails that invaded, the 3' ends are still in a position to prime the synthesis of both new nucleotide strands. Hence this scheme can be applied to either or both polarities of single-strand uptake.

The structure shown in Figure 2E must now be resolved into two separate molecules such as those shown in Figure 2F. Three ways by which this could happen have been suggested. First, the Holliday junctions may be cleaved by an endonuclease. This may allow the event to be a cross-over or not, according to the isomeric form of the two Holliday junctions at the time of cleavage. Second, if the structure has

not yet been ligated, the new strands can be separated from the old by helicase activity. Reannealing then gives two DNA molecules, one of which contains a new duplex segment. Third, the action of topoisomerases may unwind the strands between the two Holliday junctions so that the two junctions approach each other, eventually merge and disappear. The last two mechanisms predict that the outcome will not be a cross-over. Either could explain why the proportion of repair conversions that include a cross-over is low.

By any method of resolution, the overall effect of double-strand break repair is that the damaged information has been replaced by copying an undamaged homologous sequence. This nonreciprocal transfer of information constitutes a mechanism of conversion. The model offered in **Figure 2** also includes lengths of heteroduplex DNA, so that within the double-strand break repair mechanism there is also room for conversion based on heteroduplex formation and mismatch repair.

Whether the operation of recombinational repair is dependent on the formation of double-strand discontinuities is unknown. Such events might be initiated by any single-stranded region or by unbroken regions. There may be many different configurations of recombination events occurring in response to varying circumstances. Conversely, it has been suggested that meiotic recombination events, which clearly show conversion by heteroduplex formation, were initiated by double-strand cutting.

Ectopic recombination

Ectopic recombination is recombination between homologous sequences that are not at the same position on homologous chromosomes. Ectopic recombination in yeasts occurs with a frequency comparable with the frequency of recombination in the correct homologous position. Thus one supposes that gross topological constraints do not affect the uptake of recombinogenic nucleotide strands into homologous sequences and that they will become integrated into any sequence that is sufficiently similar and extensive.

That the interacting sequences are ectopically placed has little or no impact on the occurrence of conversion between them. However, resolution of ectopic conversion into a cross-over can have significant consequences which respect to genome structure. Crossing-over between nonhomologous chromosomes leads to translocation and, in some cases, to inviable acentric or dicentric chromosomes. Out of phase crossing-over among repeated sequences causes changes in the number of repeats. Intramol-

ecular ectopic crossing-over gives rise to an inversion of the intervening sequences if the ectopic homology is inverted, and to a deletion, in the form of a ring, if the homology is in direct orientation.

Fidelity of conversion

The context in which concepts of conversion are related to immunological phenomena (at least in chicken and sheep B cell diversification) apparently requires that the conversion mechanism involved is imprecise. Almost all the experiences of those working with recombination in meiotic cells, somatic cells or prokaryotes is that conversion is extremely precise. The ends of the converted length are correctly placed so that there is neither addition nor deletion and no novel substitution mutations are found within the converted length. Exceptions of which we are aware include detection of low frequency mutations associated with recombination in *E. coli* and yeast, which have been attributed to errors during DNA synthesis associated with recombination (discussed below). However, mammalian ligase activity does make nonsequence-specific joints and so could account for the observed imprecision. Conversely, since this apparent imprecision was deduced by sequencing recipients of conversion and potential donor sequences in chicken, it is possible that those changes attributed to nontemplated mutations arise by precise conversion from pseudogenes or small partial gene homologies in as yet unsequenced regions. A third possibility is that vertebrate cells may also make DNA synthesis errors associated with recombination.

How similar must sequences be to recombine?

In any model for conversion or crossing-over, base pairing is the mechanism by which two molecules are held in precise enough register to recombine. *In vitro*, the *E. coli* protein, RecA, will promote base pairing of sequences differing up to 30% in nucleotide composition. Paradoxically, *E. coli* recombination *in vivo* exerts a tighter stringency on the extent to which two sequences may differ and still recombine; sequences sharing as much as 80% similarity do not enjoy homologous recombination.

How do cells discriminate against recombining partially homologous (homeologous) sequences? Because RecA can form homeologous heteroduplexes *in vitro*, M. Radman postulated that the barrier to homeologous recombination might occur after base pairing of the recombining DNA strands. Radman proposed that mismatch repair proteins, which

recognize and bind to mismatched bases, might be responsible for preventing homeologous recombination by blocking the processing of the heteroduplex, by destroying it, or by 'unzipping' it. Support for this hypothesis has come from the finding that sequences sharing 85% similarity will recombine in mutant cells that lack mismatch repair. In addition, mismatch repair proteins have been shown to block RecA-promoted strand exchange between homeologous DNAs *in vitro*.

Do cells regulate the stringency of their homology requirements for recombination? If cells could turn their mismatch repair systems on and off, they could control the degree of sequence similarity required for conversion and crossing-over. In the first edition of this encyclopedia, we suggested that such a mechanism may allow conversion by partially homologous pseudogenes. In chicken B cells, the 'mutations' that give rise to novel immunoglobulin chains include replacements, conversions, of the previous sequence by pseudogene sequences resident elsewhere in the genome. B cells may be able to recombine ectopic homeologous sequences because they are differentiated into a state of relaxed stringency of homologous recombination. According to this proposal, this differentiation is effected by shut-down of normal cellular mismatch repair. There is now good evidence that mismatch repair proteins are downregulated in *E. coli*. They decrease during a recombination-dependent, but nontemplated, mutation process called 'adaptive' mutation.

Recombination and mutation

The recombinational mechanism for mutation discussed above also accounts for other cases of high-level mutagenesis induced by physiological stress and for activation of otherwise cryptic genes under states requiring function of those genes. Physiological induction of both phenomena has been documented in bacteria and yeast ('adaptive' mutations). At least some of the bacterial adaptive mutations form using a recombination-dependent mechanism that is unlike diversification of V genes in chicken and sheep in that the mutations are nontemplated. The bacterial recombination-dependent mutation mechanism includes formation of DNA double-strand breaks, recombination, DNA polymerase errors which are hypothesized to occur during synthesis associated with recombination, and also a downregulation of

mismatch repair such that the polymerase errors persist to become mutations. Also recently, a direct association of apparently nontemplated mutagenesis with recombined DNA in yeast has been reported. In the bacteria, a special physiological state of active mutation and recombination seems to occur. This emerging picture suggests the likelihood of multiple roles of recombination in the genetic changes important to immunological phenomena and illustrates the multiple levels at which cells can regulate their ability diversify when it is beneficial to do so.

GENE THERAPY

Claude Bagnis and **Patrice Mannoni**, Gene Therapy Center, Institut Paoli-Calmettes, Marseille, France

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Regarding possible relationships between genetic dysfunctions and pathologies, the goal of gene therapy is to promote a therapeutic activity by transferring new genetic information either into affected cells or tissues, or into accessory cells. Treatment of inherited pathologies or some acquired diseases, such as cancers, degenerative syndromes or viral infections, could be envisaged with this new strategy (Figure 1).

Gene therapy and immunology are highly interactive fields. First, genetic mutations responsible for some immune deficiencies or disorders have now been well characterized and could benefit from the use of a therapeutic gene transfer. Second, in patients with cancers, manipulation of tumor cells and/or immunocompetent cells in order to induce immunogenicity and trigger or increase an immune response could be a way to control proliferation of malignant cells.

Gene transfer tools

Numerous approaches to transferring new genetic information into target cells have been tested. Among them, viral vectors have been extensively used, taking advantage of the natural ability of genome viruses to cross the cell membrane and express exogenous coding sequences in eucaryotic cells. The most widely used viral vectors derive from retroviruses, adenoviruses, adeno-associated viruses (AAV) or poxviruses and are obtained by replacing viral sequences coding for trans-active proteins responsible for viral replication (i.e. gag, pol and env for retroviral vectors) with the gene(s) of interest. Expression of the transgene(s) can be controlled by viral elements and/or exogenous promoters. Transgene-containing defective viral particles are produced by trans-complementing cells engineered to constitutively express viral proteins absent from vectors (packaging cell lines). Retroviral vectors, and in some instances AAV-derived vectors, in contrast to adenoviral vectors, promote integration of the viral construct in the target cell genome and vertical transmission of the new genetic information. In the same way, to overcome some of the natural barriers associated with these vectors, several additional viral systems are now under development. Baculovirus, human immunodeficiency virus, herpes simplex virus, foamy virus, influenza virus, hepatitis B virus,

Sidbis/Semliki forest virus, spumavirus and simian virus 40 derived vectors can be foreseen as interesting candidates for transferring genetic information. Similarly, naked DNA, either alone or associated with lipidic particles, proteins or defective viral elements, represents an alternative to viral delivery of a transgene. In these vectors, genes of interest, placed under control of an eukaryotic promoter, are included in a plasmid backbone with a bacterial replication origin and an antibiotic resistance expression unit necessary for large-scale production. Naked DNA vectors have already been considered for clinical trials and rapid evolution in this field is anticipated.

Triggering immune reaction against cancers

Antigen presentation, cytokine-mediated cell activation and receptor–ligand interactions are interactive pathways able to induce normal immune responses. Failure of the immune system to direct a therapeutically efficient immune reaction against tumor cells can be due to insufficient effector cell activation. Experimentation and clinical trials based on these concepts, alone or in combination, have been developed to induce antitumor responses by manipulating either tumor or effector cells (Table 1).

Tumor antigen

A number of antigens encoded by genes of the MAGE, BAGE and GAGE families can be recognized by cytotoxic T lymphocytes (CTLs) in a wide range of tumors. These antigens are not expressed in normal tissues and are presented to the T cell receptor in the context of HLA. Other tumor antigens result from mutations or recombinations of ubiquitous genes such as p53, HLA-A2 or CASP-8. One can hypothesize that different or increased presentation of these antigens by the tumor cells themselves, or by antigen-presenting cells (APCs) such as monocytes-macrophages or dendritic cells can activate the immune reaction directed against cancer cells. Thus, increased immunogenicity of tumor cells has been monitored through a direct pulse of antigenic peptides or transfer of sequences coding for target antigens into tumor cells or into APCs. This approach parallels DNA vaccine models dedicated to infectious diseases.

Cytokine gene transfer

Most of the cytokines do not have a direct effect on the tumor cells but can induce a marked antitumor effect *in vivo* by initiating or potentiating specific and nonspecific host responses against tumors. Use of cytokines in this context, such as interleukin 2 (IL-2), IL-4, interferon α (IFN α) and IFN γ , has already proved efficient in the treatment of some cancers. However, lack of or low activity of systemic delivery of cytokines and toxic side-effects were observed. Therefore, transfer and expression of a cytokine gene into tumor cells would allow *in situ* delivery of the product and should direct cellular responses against the tumor. Many animal studies have demonstrated that production of cytokines, such as IL-2, IL-4, IL-7, IL-12, granulocyte-macrophage colony-stimulating factor (GM-CSF), IFNs or tumor necrosis factor α (TNF α), by transduced tumor cells elicits a host antitumor response and, in some cases, a memory response against a rechallenge with the same tumor. Clinical trials based on these approaches validated

by animal studies have already been developed. Although feasibility and absence of toxic effects have been demonstrated, until now no clear therapeutic benefit has been observed and only a few objective clinical responses have been reported.

Use of effector cell costimulatory molecules

Interaction of the CD28 receptor and its ligands B7 (CD80, CD86) produces a synergistic second signal for T cell activation and cytokine production. It has been determined that absence or low expression of B7 molecules on tumor cells could prevent T cell-mediated killing and that re-expression of this molecule at the surface of tumor cells could improve recognition and activate immune-mediated killing. Successful animal models have been developed. Assuming the possibility of teaching tumor cells to 'present themselves' in patients, Nabel and colleagues injected plasmid DNA coding for B7 directly into melanoma tumor cell masses and observed a correlation between expression of the transduced B7

gene and presence of specific T cells in tumor masses *in vivo*. Expression of CD95 ligand (Fas ligand) on tumor cells could also induce rejection of tumor cells by activating neutrophils.

Dealing with GVHD and GVL effect

A lower percentage of leukemia relapse is observed when allogeneic transplantation is associated with graft-versus-host disease (GVHD) which leads to the concept of a graft-versus-leukemia (GVL) effect. GVHD and GVL are probably mediated by the same subsets of T lymphocytes and the difficulty lies in establishing a balance between the GVL effect and the GVHD, which is associated with high morbidity and mortality.

Retroviral transfer of a suicide gene, such as the herpes simplex virus-thymidine kinase gene (HSV-TK), whose product induces sensitivity to ganciclovir, into donor T lymphocytes raises the possibility of controlling the GVHD. Reimplanted in combination with the stem cell graft, or at the time of relapse, ganciclovir-sensitive allogeneic T lymphocytes can induce a GVL effect and, if necessary, can be eliminated by injection of the drug if toxic side-effects endanger the patient's life. Considering the proliferative status of activated T lymphocytes, persistence of the suicide gene in the T lymphocyte is promoted by retroviral vector integration. Phase I clinical trials are now in progress.

Immune deficiencies or immune disorders and gene therapy

Inherited immunodeficiency diseases

Severe combined immunodeficiency diseases (SCIDs) were found to be associated with classical genetic defects. Lack of expression of adenosine deaminase (ADA), γ c cytokine receptor chain gene, p47 phox protein (in chronic granulomatous disease), Zap70 kinase and WASP protein (in Wiskott-Aldrich syndrome), could be restored by gene transfer and expression in appropriate target cells of a correct version of the gene involved in the pathology (Table 2).

Acquired immune deficiency syndrome

Acquired immune deficiency syndrome (AIDS), which results from the consequences of reactivation and spread of the human immunodeficiency virus (HIV), can be considered as an acquired genetic disease, assuming that HIV acts as a deleterious complex gene. Several blockades of the replication cycle have thus been proposed and include expression of antisenses, negative dominant mutated viral proteins, expression of protein fixation site decoys to compete

with natural sites present on the provirus, regulated production of IFN α and IFN β able to interact with viral production, intracellular synthesis of neutralizing antibodies against viral proteins, and expression of ribozymes able to specifically cleave RNA viral genomes. In addition, gene therapy vaccine approaches are now under development. Even if T lymphocytes were first proposed as target cells, it appears that difficulties in genetically modifying this cell population *ex vivo* when derived from HIV-positive patients dictated the consideration of hematopoietic progenitors as target cells and retroviral vectors as gene transfer tools to promote therapeutic activity in cell lineages involved in HIV infection. This approach would have the significant advantage of allowing therapeutic information to persist during the lifespan of the patient and of expressing the transgene of interest in dendritic cells and macrophages as well as in CD4⁺ T lymphocytes (Table 2).

Autoimmune diseases

Autoimmune disease is mediated by cellular and/or humoral responses self antigens expressed in normal cells or tissues. Induction of T cell tolerance specific for self proteins involved in autoimmune disease can prevent pathologic effects. This has been accomplished experimentally to treat induced immune-mediated diabetes by gene transfer and expression of autoantigens in bone marrow cells reinfused into animals. In addition, TNF α and IL-1 are known to be key mediators secondary to the leukocytic infiltration in rheumatoid arthritis. Blocking of IL-1 deleterious effects has already been demonstrated using either *ex vivo* transfer of IL-1 receptor antagonist gene in synovial cells prior to reinfusion into the knees of an antigen-induced arthritis rabbit model, or direct *in vivo* adenoviral transfer of soluble type I TNF α receptor or IL-1 receptor-IgG (immunoglobulin G) fusion gene. Clinical trials are now in progress (Table 2).

Animal models: a step forward and a trap

Gene therapy would not exist without animal models. Many biological concepts underlying gene therapy, and especially those using immunological tools, arise from animal studies. Impressive eradication of tumors by activation of cellular responses mediated by effectors such as CTLs, natural killer cells, macrophages, eosinophils and neutrophils were observed in animals reinfused with cells expressing transduced genes for cytokines or other stimulatory molecules. Conversely, use of the same concepts in human clinical trials has given relatively poor results in terms of

therapeutic effect. These differences mainly arise from the differences in health status between end-stage patients and animals bearing freshly implanted tumor cells, and the possibility that immunological pathways used differ between animal and human. Technical problems, such as transduction efficiency, expression of the transgene in the majority of tumor cells and large scale procedures with human material, have still to be resolved.

Although toxicity of a transgene product or inefficiency of a treatment could be checked with animal models, strategy developed in an animal model directly transposed to a clinical trial should be considered very carefully. In addition, for cancer gene

therapy animal models with naturally occurring tumors could be more relevant to the human context.

Immune reactivity against vector proteins and transgene products

Gene therapy will probably require multiple injection of vectors or of genetically modified cells, which emphasizes the possibility of immune-mediated inactivation of the treatment. Retroviral, AAV and plasmid vectors seem to be insufficiently antigen to induce an immune reaction by themselves. It is worth noting that major concerns have been raised about immune reaction against viral proteins encoded by

the remaining genome of adenoviral vectors, and work is now in progress to construct vectors devoid of viral sequences (gutless vectors) or which are less immunogenic. Immune reactions against heterologous transgene products, which can synergize with immune reactivity directed against viral vector protein, have already been described for all types of vectors.

Perspectives

The therapeutic benefit which would arise from gene therapy in treatment of cancers or immune disorders depends on both technical improvement and evolution in immunological concepts. Transduction efficiency and long-term expression of the transgene have already been emphasized as key problems in gene therapy procedures. Development of new vector strategies, targeting of cells to be transduced and control of expression of the transgene, using tissue specific promoters or inducible constructs, are now under investigation in order to overcome some aspects of these problems. In addition, full characterization of the cytokine network and cytokine functions in the human system would help to better define possible therapeutic utilities of some molecules in cancer therapy, and develop more therapeutically efficient combinations between the disease to be treated and the transgene used. In addition, even though most of the treatments to date have been performed by *ex vivo* genetic modification of the target cells, important efforts are under development to deliver new genetic information *in vivo*, thus emphasizing the need for cellular and molecular targeting in order to induce new functions restricted to the target cells.

GENETIC ANALYSIS AT THE MOLECULAR LEVEL

Philippe Kourilsky and **Laurent Gopin**, Laboratory of Molecular Biology of the Gene, Pasteur Institute, Paris, France

With any genetic approach, one major requirement is to develop genetically homogeneous collections of organisms (e.g. mouse strains), cells (e.g. clones of T cells or B cells), or DNA molecules. DNA cloning techniques first relied on bacterial genetics (e.g. transducing phages) and then on genetic engineering methods. The latter were initially perceived as a breakthrough for the production of foreign protein by microorganisms, but it soon became obvious that they offered a quasi-general solution to the amazingly difficult problem of gene purification. The concomitant development of DNA sequencing in 1975 allowed the determination of the sequence of a purified gene, i.e. its structure, or more precisely, its chemical formula. Ten years later (1985), an *in vitro* cloning procedure was discovered. The polymerase chain reaction (PCR) enables amplification of tiny amounts (actually down to one or a few molecules) of DNA millions of times in just hours, thus allowing minute samples of DNA to be analyzed. Purified genes can be mutated *in vitro*, at random or specifically, thanks to synthetic oligonucleotides. Mutated or not, they can be introduced into living cells in culture by transformation or transfection, or used in the generation of transgenic animals. Targeted genes can also be disrupted in embryonic stem (ES) cells by homologous DNA recombination techniques. The resulting mutant ES cells can then be introduced into blastocysts of normal mice to generate chimeric embryos, which may develop into chimeric animals. Homozygous animals for the mutation are obtained by selective breeding over several generations. More recently, using different recombination systems, it has become possible to inactivate genes in a tissue-specific or inducible manner. Thus, a wide battery of methods and techniques is now available for genetic

analysis at the molecular level. The structural and functional analyses of genes can be bridged in a variety of ways. These powerful tools have been, and will go on being used productively in immunology. Techniques and protocols have rapidly been formalized into simple recipes and the necessary reagents and instruments have been commercialized quickly, such that many of these molecular analyses have become a matter of routine in a large number of laboratories. The following overview of these molecular approaches is illustrated by a few selected examples.

Analysis of gene structure

For the analysis of gene structure, cloning is mostly performed in *Escherichia coli*, where a variety of sophisticated cloning vectors facilitate cloning, sub-cloning and sequencing. Difficulties in the isolation of new genes usually arise when probes are lacking and 1) genes are poorly expressed (because the mRNA is rare and the corresponding cDNA is difficult to isolate, while the information on the protein product is scarce and hard to gather), 2) genes are exceedingly large (the gene responsible for Duchenne muscular dystrophy is over 2000 kb long), and 3) large-scale cloning and sequencing is involved. However many of these problems have been overcome by the use of PCR and other technologies embedded within the genome mapping and sequencing approaches. New instruments and the appropriate software are actively being developed in the frame of 'human genome' projects. A huge mass of information is being deposited in databanks. The entire repertoire of variable gene segments of antibodies and T cell receptors will soon be available in several

species (see below), with the additional prospect of comparing the corresponding loci in various species or various individuals of the same species.

Analysis of gene expression

Studies of the expression of endogenous genes can be performed in a variety of ways. Messenger RNAs can be assayed by hybridization with probes in northern blot experiments or with reverse transcription polymerase chain reaction (RT-PCR). Other sophisticated assays, useful to discriminate between alternatively spliced mRNA from the same gene, or mRNAs produced by close members of a multigene family, involve RNases and/or S1 nuclease to detect mismatches. Carefully controlled hybridization with oligonucleotides can detect a simple mismatch (and can also be used in northern blots, as well as in Southern or dot blots to analyze genomic DNA). When the sequence studied is already known, specific oligonucleotides can be derived and PCR techniques used to identify different messenger RNAs, mutations or small deletions (by direct sequence of the PCR product, digestion with restriction enzymes, hybridization of product with a specific probe, single-strand conformational polymorphism, etc.). *In situ* hybridization (with a sensitivity of about 10 copies per cell) and *in situ* PCR (for detection of low copy events, point mutations, etc.) open many possibilities in oncogenesis, embryology, RNA trafficking and detection of viral diseases.

Of course, the gene product itself can be assayed by its activity or by its specific binding to appropriate ligands such as antibodies. Detection of gene expression by molecular biology techniques associated with the detection of other gene products by flow cytometry analysis may be useful in some cases. For example, flow cytometry analysis followed by cell sorting and single-cell PCR of rearranged immunoglobulin or TCR genes allows analysis of antigen specific T and B cell repertoires in the course of immunization. In the same way, the phenotype of virus-infected cells (by human immunodeficiency virus (HIV), for example) can be determined by a combination of the intracellular PCR technique with fluorescent labeled oligonucleotides and flow cytometry analyses. This approach also applies to cytokines and other genes of immunological interest.

Apart from the mere observation of physiological or pathological situations, gene expression studies are widely used in structure-function relationship analyses, which require that the gene possibly altered or mutated is introduced into a living cell or organism (purely *in vitro* systems are most of the time inadequate). There are multiple empirical ways of

introducing DNA into cells. The most usual one is the calcium phosphate technique. Fusions with bacterial protoplasts, red blood cell ghosts and lipid vesicles are also used. Electroporation, as well as cationic liposome-mediated transfection (lipofection) are seemingly better controlled. Microinjection requires skill, and is not appropriate for large-scale experiments. Infection with viruses is another route. Thus, recombinant vaccinia viruses will express the recombinant protein in many different cell types, but in 2–3 days cells die from infection. Retroviral vectors for gene transfer have been more difficult to handle than was initially anticipated. Nevertheless, they do fulfill the requirements for efficient gene transfer without irrelevant alteration of the cell properties, and constitute useful tools. They have already been used in animals to transfer genes into different permanently dividing tissues such as the hematopoietic tissue or the liver. Immunization of animals with naked DNA (usually into the muscle) or formulated DNA is a relatively new means of assessing the immunogenicity of gene sequences.

The generation of transgenic animals has become a routine operation. However, it is more difficult to make transgenic mice in a homozygous congenic background which is necessary in many experiments of immunological interest. In such gene transfer experiments, the transferred DNA is added to a pre-existing genome and integrates more or less at random. Even when it carries homologies with resident genes, it is usually not substituted to them. Furthermore, the level of expression and the tissue specificity of the injected construct are not efficiently controlled. Animals often display unexpected phenotypes but these can turn out to be quite useful. For example, the ubiquitously expressed hydroxymethyl CoA reductase promoter yields levels of expression which vary even in animals derived from the same founder.

The powerful gene targeting technology has first been used to destroy specific genes in so called knockout mice. In its early version homologous recombination between exogenous DNA and its endogenous homolog in pluripotent mouse embryonic stem cells was used to disrupt the latter by insertion of a neomycin resistance gene. However, the insertion of a *neo^r* gene sometimes disturbs the surrounding chromosomal organization and gene expression. To overcome these problems, a 'cleaner' way to create mutations has recently been described. This method is based on the DNA-site specific recombination of the Cre/loxP system from the bacteriophage P1 or the yeast recombination system FLP/FRT. Two loxP (or FRT) sequences are introduced in predefined positions around the targeted

sequence by homologous recombination. The targeted sequence can then be deleted by recombination mediated by Cre/loxP (or FLP/FRT). This approach has several advantages since the mutated gene locus does not contain the selection marker and genes can be inactivated in a tissue-specific or inducible manner. Recombinant mice containing Cre/loxP sequences around one defined gene can be bred with other mice transgenic for the Cre enzyme gene under the control of a tissue-specific or inducible promoter (see **Figure 1**). Since lymphocyte differentiation and activation are processes characterized by complex but coordinated programs involving many molecules, targeted gene disruption appears to be a tool of choice to study the unique role played by each one among the others. This approach has so far revealed the somewhat unexpected plasticity of the immune system to adapt and compensate for the loss of key molecules. As the list of genetically modified mouse strains is growing on a monthly basis, no doubt more surprises will be forthcoming in our understanding of lymphocyte development and function in host defense.

Analysis of gene regulation

Another body of methods and techniques has been developed to analyze the mechanisms by which isolated genes are regulated, particularly at the transcriptional level. A usual scheme involves the deletion analysis of the promoter region attached to a reporter gene coding for an easily assayable product (e.g. chloramphenicol acetyl transferase, β -galactosidase, luciferase, peptide tags as ligands for specific antibodies, etc.). Once important regions are identified, the promoter is chopped into pieces and scanned for elements which positively or negatively modulate its activity, such as enhancer or enhancer-like sequences. Often, the putative important elements are polymerized *in vitro* (sometimes in the form of synthetic oligonucleotides) and assayed *in vivo* in appropriate expression vectors, or as competitors. Then starts the hunt for DNA-binding proteins, first with the less sophisticated, but artifact-prone, band shift (gel retardation) assays, followed by DNA footprints and methylation interference experiments, in which contact residues between the

Figure 1 Generation of tissue-specific knockout mice based on the Cre/loxP DNA site-specific recombination system from bacteriophage P1.

protein factor and the DNA sequence are identified. Next, the DNA binding protein can be purified by a combination of conventional and affinity chromatography techniques (using the polymerized DNA sequence coupled to a column). Ultimately, the purified protein can be microsequenced, allowing the deduction of 'back-translated' probe or primers and the corresponding gene may be cloned.

An alternative strategy employs libraries of cDNAs cloned in *E. coli* expression vectors such as λ gt11 and an *in situ* assay allowing the detection, in the phage plaques, of specific binding of a labeled antibody raised against the protein of interest, or of labeled DNA sequence representing the binding site of the protein. When successful, this approach is much faster, but the identification of the encoded protein can remain elusive. The cloned factors can then be studied in many ways, and the synthesis of altered forms (truncated, mutated, fused, etc.) in *E. coli* or *in vitro* (e.g. in T7 RNA polymerase-based expression systems, involving cell-free translation procedures) is the next avenue of exploration.

The double hybrid system in yeast is a useful way to detect proteins capable of interacting with a known factor and results in the immediate availability of the cloned genes for these interacting proteins. One hybrid consists of the DNA-binding domain of yeast transcriptional activator proteins GAL4 or LEX A fused to the known protein; the other hybrid consists of the GAL4 or LEX A activation domain fused to protein sequences encoded by a library of genomic DNA fragments. Interaction between the known factor and a protein encoded by one of the family plasmids leads to transcriptional activation of a reporter gene containing a binding site for GAL4 or LEX A.

An important and difficult task is to compare the factors, in the course of their characterization, to others, cloning being the only safe way to decide whether factors are identical or different. Another essential question is to understand the relationships between DNA-binding proteins which attach to the same promoter sequence. Most human and mouse promoters contain sites that can bind several different factors (some of them even bind to each other), and the spectrum of bound proteins may vary in different cells and tissues, depending upon external stimuli. It should not be forgotten that regulatory elements can be found far upstream of genes, within genes, or downstream, and that many possibilities for post-transcriptional regulation have been found. It is difficult to assess the *in vivo* significance of one or a set of element(s) recognized as important *in vitro*, and the use of transgenic or knockout mice then becomes necessary.

Large-scale production of proteins

Another facet of molecular genetics is the ability to produce proteins in relatively large amounts from a cloned gene. Since this may be of obvious medical and economic interest, considerable efforts have been invested in a variety of production systems. The most popular include *E. coli* and yeast transformed with appropriate plasmids (expression often being inducible), insect cells infected with recombinant baculoviruses, and mammalian cells transfected with genes together with selectable (and sometimes amplifiable) markers, or infected with recombinant viruses (such as retroviruses and vaccinia viruses). Molecules of immunological interest have also been produced in plants (e.g. tobacco). The level of expression is most of the time unpredictable and the field remains very empirical. Numerous parameters are involved, including the rate of degradation of the foreign protein, its solubility or insolubility (cf. the formation of inclusion bodies), etc. Solubility can be manipulated by the choice of vector, cloning sites, host cells, or, in the case of bacterial expression, by cloning the desired sequence downstream of a bacterial signal sequence (like *pelB*) for potential periplasmic localization. Production of a fusion protein can also help in improving solubility of the recombinant molecule, and results in easier purification (an oligohistidine domain can be added for purification over nickel column, a peptide tag for immunological detection and affinity purification, etc.) A protease cleavage site (thrombin, factor Xa, enterokinase) introduced between the sequence of interest and the tag, may allow removal of the upstream domain by treatment of the fusion protein with a protease.

Accordingly, different proteins are expressed at widely different levels, and even minor changes can result in differences of orders of magnitude in their expression. (Vaccinia viruses are, perhaps, one of the most reproducible systems.) Contrary to initial beliefs, the problems often lie with RNA structure and splicing (aberrant splicing is a frequent source of problems) and/or translation (initiation, propagation and, perhaps, codon usage) while the efficiency of transcription is often not limiting. One should keep in mind that a genetically engineered protein may display minor differences (mostly due to post-translational modifications) to the natural one. These differences may be functionally important *in vitro* or *in vivo* (e.g. the rate of *in vivo* clearance of recombinant nonglycosylated interferon γ (IFN γ) is higher).

Expression of cloned genes is essential to overcome the problems associated with the purification of trace amounts of products of immunological importance. This holds true for interleukins and intracellular

regulatory factors, some of which have been produced in sufficiently large amounts for biological, biochemical, crystallographic studies or clinical trials. Another dimension has been added with the expression of antibodies and other polymorphic molecules in microorganisms (either as spontaneously assembled segments, or as single-chain molecules in which the variable regions are held together with a spacer sequence, single-chain TCR and MHC molecules have also been produced). Combining PCR technologies with the expression of light and heavy antibody chains fused to phage coat protein (fusion to pIII leading to 3–5 copies located at the tip of each phage or fusion to pVIII giving 2500 copies per phage), it is now possible to generate combinatorial libraries of antibody specificities with diversity in excess of 10^{10} , either from the mouse (immunized or naive) or human (usually naive) B cell repertoire. With 3 or 4 rounds of selection through column or plate-coated antigen, following amplification in *E. coli*, phages expressing a desired specificity can be isolated (differential selection using cells is more difficult and limits the use of the technology). One can imagine that these libraries are large or almost large enough to allow selection of any specificity which one may need. Micromolar antibody affinities which are often obtained are too low for most practical applications but affinity maturation can be mimicked *in vitro* using error-prone PCR or mutagenesis, followed by selection for higher affinity.

Repertoire-selection technology has also been used to select peptides. Random peptide libraries are constructed by ligation of a degenerate oligonucleotide insert to a chosen display vector. Once created, epitope libraries are universal reagents that can potentially be used to identify ligands for any available receptor (antibodies, MHC molecules, concanavalin A, etc.)

The specificity of molecular genetics in immunology

The above survey could apply to several fields of biology (developmental biology, neurobiology, etc.). To a certain extent, immunology brings about a number of specific problems, some of which are summarized below.

As in all fields of biology, and thanks to molecular methods, the 'natural history', or descriptive aspects, of immunology are expanding very rapidly at the gene level. It so happens that the immune system involves the largest of all known multi- and super-multigene families. Thus, sequence determinations, comparisons and analyses within a given species, and between different species, constitute an extremely

interesting and valuable body of data for evolutionary and polymorphism studies. Correlatively, structural analogies at the protein level permit computer-aided protein modeling to be used in a relatively robust way. This was illustrated by work on antibodies and MHC molecules in which, from a small number of known crystallographic structures, relatively accurate protein models were derived.

Second, the immune system is the only system so far to display such high polymorphism and diversity. This relates to the dynamics of the large multigene families (MHC genes, V regions of antibodies and TCRs) and of the selective forces involved. Furthermore, the combinatorial recombination of antibodies and TCRs raises the question of potential, actual or available repertoire at any given time in a given individual. Molecular genetics (e.g. PCR) is now providing a powerful support to the study of T cell repertoires, previously hampered by the difficulty in obtaining clonotypic reagents. With a combination of PCR reactions involving C_{β} , V_{β} and J_{β} primers, and size measurement providing the lengths of the CDR3-like regions of β chains, one can identify T cell repertoires from amongst 2000 clonotypes. Quantitative PCR has been greatly improved and is very helpful for measuring, for example, interleukin transcripts in biological samples, including human biopsies.

Finally, thanks to the progress made in cloning (animals, cells and genes), the immune system now appears as the most complex system for which the most detailed description of the constitutive elements is available. It is common to emphasize the reductionist attitude of molecular biology which, by essence, looks at a single element (gene or protein) at a time. It is interesting to perceive how, since 1976 (the cloning of an immunoglobulin gene by Tonegawa), genetic analysis at the molecular level has penetrated a field initially dominated by systemic studies. It is fascinating to observe how molecular studies have produced enough knowledge to begin drawing integrated views of the molecular elements, which it is becoming possible to try to match with their systemic behaviors.

GENETIC ANALYSIS AT THE PHENOTYPIC LEVEL

M Ilyas Kamboh, Department of Human Genetics, University of Pittsburgh, Graduate School of Public Health, Pennsylvania, USA

The words 'genotype' and 'phenotype' were first used in 1911 by a Danish botanist, W Johannsen, to elucidate the relationship between the genetic material and its resulting product, the phenotype. With the advent and application of sophisticated molecular techniques, the concept of genotype (gene) has become more clear. An individual's *genotype* refers to its genetic constitution: either the whole genome, which consists of full DNA content on its chromosomes; or, more specifically, a single gene, which is a single functional section of DNA on one specific chromosome. The term *phenotype* is, however, more complicated: it not only represents the expression of the genotype into biochemical, physiologic, structural and physical traits, but also depends on the interaction between the genotype and environmental factors in which the organism develops. In comparison to the individual's genotype, which is transmitted to daughter cells either through somatic (mitosis) or germ (meiosis) cell divisions, a given phenotype may or may not be directly inherited.

Some phenotypes, like monogenic (single-gene) traits, are largely genetically controlled; other phenotypes, like multifactorial traits, are the result of both polygenic (multiple genes) and environmental interactions. While the monogenically controlled phenotypes remain largely unaffected by environmental changes the multifactorial phenotypes are subject to changes over time depending on the environment to which organisms are exposed.

The molecular flow of information determines the nature of an individual's phenotype and proceeds from DNA to RNA and then to protein. In order to transfer its genetic constituent (genotype) to a specific gene product (protein), a portion of DNA (gene) is first transcribed into a messenger RNA, which by acting as a template translates the genetic information into a specific protein molecule. The basic unit

of the genetic code or information is a codon, which consists of three nucleotides, that code for a single amino acid. There are 20 different kinds of amino acids, which are the building blocks of the polypeptide chain(s) of a protein. The structure of protein is also influenced by post-translational changes, enabling it to be processed further.

Structural abnormalities in proteins occur due to mutations in corresponding genes. Mutations, which are inheritable, can either be minute or gross. The most common mutations are of the former type and referred to as point mutations, causing a single base change in the codon, that may change the amino acid sequence in the polypeptide chain and result in a variant protein phenotype. If structural changes occur in the functional domains of a protein vital to the organism's normal physiology, these mutations may lead to a clinically abnormal phenotype. However, most of the mutations, as they occur frequently in the population, are neutral because phenotypic changes due to mutations are equally functional. The existence of two or more common and different forms of either structural, biochemical, physiologic or physical phenotypic traits in the population is termed polymorphism. The basis of these multiple phenotypic forms of a given trait is the existence of multiple alleles at the relevant gene locus. If both parents contribute identical alleles, an individual is said to be homozygous; if the alleles are different, it is called heterozygous.

In the following sections, the concepts of genetic analysis at the phenotypic level is reviewed briefly using a few selected examples with the emphasis being placed on genetically determined variation in the structure of proteins and the role of such variation in affecting monogenic and polygenic phenotypic traits and human diseases.

Phenotypic variation in the structure of proteins

The concept of one gene—one polypeptide implies that the synthesis of each polypeptide chain of a given protein is controlled by a single gene. Thus, the structure (phenotype) of a protein is directly under genetic control. In protein structural studies, the term phenotype often refers to genetically controlled different structural forms of a protein. Analysis of genetically determined phenotypic variability in protein structure became possible with the advent of various electrophoretic techniques. Early work on protein polymorphism focused mainly on enzymes in humans (Harris) and *Drosophila*, a fruit fly (Lewontin and Hubby). Using these conventional methods of electrophoresis, Harris estimated that approximately one-third of all possible amino acid substitutions in the polypeptide chain of proteins could be detected. However, the early methods were not sensitive enough to detect phenotypic differences in molecules having similar or identical molecular size and conformation but different isoelectric points (a point at which protein carries no net electrical charge).

In the early 1980s, the application of the isoelectric focusing (IEF) technique made it possible to detect minute differences of isoelectric points between various protein isoforms, thus allowing the observation of previously undetectable phenotypic variation. In addition to the charged amino acid substitutions, the IEF technique can also detect some neutral amino acid substitutions in the protein structure. Approximately 40% of mutations resulting from single-base substitution would lead to electrophoretically detectable changes in charged amino acids, while another 40–60% would involve neutral-to-neutral amino acid substitutions. In addition to the progress in separating proteins, advanced protein detection methods have also played a major role in observing protein phenotypes. The development of immunoblotting or western blotting techniques has replaced most other detection methods because of their sensitivity and versatility. Today, there are about 100 plasma proteins and red cell enzymes that show electrophoretically detectable polymorphisms in humans.

Alleles coding for protein phenotypes are expressed in a codominant fashion because both the homozygous and heterozygous forms are distinguishable and both pairs of alleles are fully expressed in heterozygotes. In such cases, the genotype can be inferred directly from the visible phenotypic patterns on the electrophoretic gels. Most of these protein polymorphisms are neutral because they do not

appear to have drastic effects on an individual's physical or biological functions.

Phenotypic expression of a single gene

In addition to the common polymorphisms not associated with any obvious phenotypic abnormalities, there are several examples of phenotypic disorders associated with genotypic changes in a single gene. These disorders are commonly referred to as single-gene or monogenic disorders. In these disorders, phenotypic variability is primarily determined at the corresponding gene locus and the effect of other loci and environmental factors, although they may be present, is not the major determinant. These single-gene phenotypes (disorders) are also known as *Mendelian* traits because they segregate in families in observation of Mendel's laws of inheritance. The inheritance and expression of these traits depend on whether the given gene is on an autosomal chromosome or on the X chromosome, and whether the expression is *dominant* or *recessive*. An allele is *dominant* when it is expressed to yield a clinical phenotype in the heterozygous state, and *recessive* when expressed only in the homozygous state. However, at the molecular level, neither of the alleles are dominant nor recessive because the gene product (protein) of both alleles is expressed in a codominant fashion. Therefore, strictly speaking, it is the phenotypic expression of alleles which is either dominant or recessive. The majority of single-gene defects involved in the manifestation of human clinical phenotypes are rare in the general population. Clinical phenotypes in these disorders result from structural and biochemical defects in proteins, such as enzymes, hormones, cell receptors, etc. By way of example, the following is a brief description of some of the common monogenic disorders.

Familial hypercholesterolemia is an autosomal dominant trait that is characterized by elevated low-density lipoprotein (LDL), cholesterol, tendon xanthomas (cholesterol-containing tumors), and premature coronary heart disease. The molecular basis of this disease is mutations in the gene coding for the LDL receptor. The LDL receptor protein, located on the surface of most body cells, plays a pivotal role in the removal of LDL cholesterol from the blood circulation. Due to mutations in the LDL receptor genes, the production and function of LDL receptors are drastically altered leading to the accumulation of LDL cholesterol in the circulation. In heterozygotes, with a frequency of about 1 in 500 in most populations, the number of receptors is reduced to almost a half. In rare homozygous cases (1:1 000 000), the number of LDL receptors is reduced drastically and

the cholesterol level can rise up to 10 times its normal level.

Other relatively common autosomal dominant disorders include Huntington disease, adult polycystic kidney disease, von Willebrand disease, and neurofibromatosis 1.

Sickle-cell anemia is a classic example of the relationship between the genotype, gene product (protein), and the phenotype of the disease. The disease is caused by a single point mutation in the DNA that codes for the β -hemoglobin chain (human hemoglobin is composed of two α chains, each containing 141 amino acids and two β -polypeptide chains, each with 146 amino acids). The sickle cell mutation results in the replacement of a normally occurring amino acid glutamic acid by valine at the sixth position in the β chain. This single amino acid substitution is the only difference in primary structure between normal and the sickle cell hemoglobins and this difference can easily be detected electrophoretically due to their different migration positions on the gel. Since sickle-cell anemia is a recessive disorder, individuals with one copy of the sickle-cell gene are phenotypically normal but are classified as carriers; while affected individuals carry both copies of the defective gene. Sickle-cell anemia is manifested by severe hemolytic anemia due to gross abnormalities in the shape and function of red blood cells. The disease is more common in Blacks, but also occurs in India and in the Mediterranean area. Among US Blacks, the carrier frequency is about 1 in 10 and the frequency of affected individuals is about 1 in 400.

An individual having abnormal hemoglobin may yet experience several other phenotypic disorders, like liver, heart, lung, brain, skeletal and gastrointestinal damage, because of the prime importance of hemoglobin in supplying oxygen to various parts of the body. At least 25 different major phenotypic disorders are known which are the direct result of abnormal expression of a single gene due to a single-point mutation leading to the replacement of one amino acid in the hemoglobin molecule. Such genes having multiple effects on several phenotypic traits are referred to as being *pleiotropic*.

Cystic fibrosis (CF) is the most common autosomal recessive disorder in populations of European ancestry with a carrier frequency of about 1 in 25 and a disease frequency of about 1 in 2500 live births. The major clinical symptoms of the CF phenotype include exocrine insufficiency of the pancreas, chronic lung disease, and elevated concentration of sweat electrolytes. The basic biochemical defect causing the CF phenotype was unknown until relatively recently when the CF gene was cloned. Analysis of the sequence of the complementary DNA (DNA synthe-

sized from a messenger RNA template) of the CF gene predicts a protein containing 1480 amino acids and termed the cystic fibrosis transmembrane conductance regulator (CFTR). Approximately 70% of the mutations in CF patients are due to the loss of a single specific codon (three nucleotides) in the CF gene on chromosome 7. Deletion of this codon results in the loss of a single amino acid, the phenylalanine at position 508 in the CFTR. As with sickle-cell disease, the change of a single amino acid in the protein structure accounts for most CF cases, indicating that the CF phenotype may not result from the complete loss of the CFTR function.

Common examples of autosomal recessive disorders include phenylketonuria, several types of glycosphingolipidoses and mucopolysaccharidoses. Similarly, several X-linked phenotypic disorders due to single-gene defects are known: common ones include glucose-6-phosphate dehydrogenase deficiency, hemophilia A, Duchenne muscular dystrophy, and color blindness.

In addition to these clinically associated phenotypes, there are large numbers of other genetically determined phenotypes whose appearance or expressions are not associated with any disorders, e.g. eye color, hair texture, attached and free ear lobes, appearance of dimples and freckles, hairs on the back of finger, and cleft chin. All these phenotypes are due to autosomal dominant inheritance, and they do not have harmful effects but account for some interindividual variation.

Phenotypic expression due to multifactorial inheritance

Most human phenotypic traits and diseases are not determined by a single-gene effect; rather they are caused by the interaction of genes and the environment, and are thus known as multifactorial conditions. The inheritance of multifactorial traits (also known as polygenic traits because of the involvement of multiple genes in determining a single trait) account for much of the normal variation (e.g. height, weight, skin color and intelligence), and many common diseases, including cardiovascular disease, diabetes mellitus, hypertension and congenital anomalies. In contrast to single-gene traits which segregate in families, familial recurrences of multifactorial traits are difficult to predict because multiple genes are involved in the expression of a phenotypic trait and the effects of genes are modulated by different environmental factors. The exact number of genes involved in determining a given multifactorial trait is unknown; but each gene contributes a small but additive effect which may combine with other

environmental factors for their final impact on the phenotype.

The genetic and environmental basis of cardiovascular disease (CVD) is one of the most extensively studied of any of the common chronic diseases in humans. There are several candidate genes whose protein products are involved in the metabolic pathways of normal cardiovascular function; and variation in these gene products may determine in individual's susceptibility or resistance to CVD. Epidemiologic studies have also identified several environmental factors putting people at risk of developing CVD, including imprudent diet, obesity and smoking. Almost half of the candidate genes are structurally polymorphic and this genetic variation can interact with the above-mentioned environmental risk factors in determining an individual's susceptibility to the disease. For example, elevated level of cholesterol is a major risk factor for CVD and about 50% of interindividual variation in cholesterol level is under genetic control. If a person inherits a group of so-called susceptible genes whose cumulative effects are to increase the cholesterol level, and if that person also consumes a highly saturated fat diet rich in cholesterol, it is very likely that they will develop the phenotype of CVD much earlier than another person who has an identical genetic profile but does not eat a saturated fat diet. In such traits as CVD, genetic impact depends on environmental exposure to determine the final phenotype.

Similarly, there are several examples of monogenic and polygenic immunological diseases which can be summarized as follows. HLA, the major histocompatibility complex, comprises multiple closely linked genes, which are highly polymorphic, and inheritance of a certain group of alleles at these loci is found to be associated with specific diseases in response to environmental changes. Some diseases associated with specific HLA alleles include type 1 insulin-dependent diabetes mellitus, ankylosing spondylitis and hemochromatosis, and several autoimmune diseases. Similarly, genetic predisposition to several immune complex diseases are associated with com-

plement component deficiencies. The mode of inheritance of most of these complement deficiencies is autosomal recessive. Some examples of other inherited immunological diseases include: ataxia telangiectasia, immunologic amnesia and severe combined immune deficiency diseases which are autosomal recessive disorders; and hypogammaglobulinemias and chronic granulomatous disease which are X-linked recessive traits.

GERM-FREE ANIMALS

Joop P Koopman, Central Animal Laboratory, Catholic University of Nijmegen, Nijmegen, The Netherlands

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Usually, all animals are associated with complex communities of microorganisms. In these animals, it is not possible to study the role of the microflora or parts of it. Germ-free animals have been developed to study the animal without interference from the microflora and to study the effects of certain floral elements.

Although the entire body surface and all the mucous membranes harbor microorganisms, most interest has centered around the intestinal microflora. A comprehensive term encompassing all forms of known host-contaminant association is 'gnotobiotic' or, for the discipline in general, 'gnotobiology'. This word has been derived from the Greek *gnotos* (known) and *biota* (all living vegetable and animal organisms). Gnotobiotic animals are derived by aseptic cesarean section or sterile hatching of eggs, which are reared and continuously maintained by germ-free techniques under isolator conditions and in which the composition of any associated fauna and flora is fully defined by accepted current methodology. Germ-free animals are gnotobiotic animals free from all demonstrable associated forms of life, including bacteria, viruses, fungi, protozoa, and other saprophytic or parasitic forms. If germ-free animals are associated with defined microorganisms, then these gnotobionts are termed monoassociated, diassociated, etc., depending on the number of microbial strains given.

The origin of the germ-free concept goes back to 1885, when Pasteur stated that life would probably become impossible if animals were deprived of their normal flora. A supporter of Pasteur's ideas at the turn of the century was Schottelius, who contributed much to the methods of rearing germ-free chickens. However, his animals were fed inadequate diets and were therefore unsuitable to study the effects of the missing flora. In 1886, Nencki was the first to attack Pasteur on theoretical grounds. About 10 years later, Nuttal and Thierfelder were the first to produce germ-free mammals. Based on the knowledge gained by these early workers, steel units for the maintenance of germ-free rodents were developed in 1946 by Reyniers and colleagues and plastic isolators by Trexler and Reynolds in 1957. Both types of housing methods are still in use on a large scale today.

Characteristics of germ-free animals

Germ-free animals not only differ from conventional animals by their absence of bacterial flora, but also by their lack of systemic responses to that flora. On autopsy of germ-free animals, most details appear to be normal. However, when the relative weights of freshly excised organs are compared, certain characteristics become apparent. In various animal species, parts of the digestive tract, notably the small intestine, its associated lymph nodes and in some instances the liver, show a lower weight in the germ-free group. Other organs, such as the heart and the brain, show little or no difference between the germ-free and normal stock. Thus, in terms of weight, the organs of the animals fall into two distinct groups: one harbors an abundant flora in normal life and shows reduced weight in the germ-free animals; the other group of organs that is normally remote from bacteria shows practically no difference between the germ-free and normal stock. A striking observation in germ-free mammals is the enlarged cecum (4–6-fold increase in weight). This cecal enlargement does not appear to impair the animal's health particularly, but indirectly the extended cecum can give rise to intestinal volvuli affecting the junction of the ileum and colon. The exact cause of the extended cecum is unknown.

Studies of basal metabolism and blood circulation in germ-free animals show reductions in these measurements of function. Compared with conventional animals, the following reductions were measured in germ-free rats: basal metabolic rate, 20%; cardiac output, 32%; blood volume, 22%; arterial blood flow to liver, 50%.

Applications of germ-free animals

Surgical application

To avoid the risk of postoperative wound infection, surgical procedures are carried out in germ-free animals in germ-free isolators. Especially in the field of intestinal surgery, germ-free animals are frequently used to study aspects of wound healing.

Oncology

Some spontaneous murine hematopoietic neoplasms are affected by the absence of a conventional

microbial environment, whereas nonhematopoietic tumors are not. Conflicting data were obtained following the introduction of chemical carcinogens in germ-free and conventional mice. The effects of the natural microflora are unclear. Germ-free animals provide an important tool of research in the fight against cancer.

Dental research

The use of germ-free animals and the principles of gnotobiology have provided much information concerning the origin of caries and periodontal disease. The flora in these animal models can be modified, giving information about the cause of both diseases. Also, treatment and prevention can be studied with the help of gnotobiotic animal models.

Microbiology

Studies with germ-free animals are carried out on a large scale to investigate the complex microecological relationships between microbes themselves and between the microbes and their hosts. One of the most important functions of the intestinal microflora for the host is the phenomenon of colonization resistance, being the force withstanding oral infections. Only the presence of many hundreds of different biotypes of microorganisms in an intestinal tract provides a 'normal' colonization resistance.

Toxicology

In an intestinal tract of a 'normal' animal, the bacterial cells outnumber the cells of the whole body. This means that an enormous metabolic capacity is present in the intestinal tract. Detoxification of a broad variety of toxic products occurs by the normal microflora. With the help of gnotobiotic animals this phenomenon can be investigated in relation to the quality of the microflora.

Nutrition

From the outset of using germ-free animals, nutrition was of utmost importance, due to the sterilization of food necessary to rear germ-free animals. The microchemical environment in the intestine is determined by three factors: chemicals in the diet, chemicals of host origin and chemicals derived by the intestinal microbial flora. By means of gnotobiotic technology, it is possible to change the factors due to diet and microflora to assess the potential impact for the microchemical environment in the intestine.

Immunology

Germ-free animals have provided us with a unique model for studying a true primary response. A reaction to an antigen to which the animal has not previously been exposed is generally considered to be a primary response. During a normal lifespan, however, animals encounter a large number of antigens in the environment that might cross-react with antigens used in investigative work. Germ-free animals can be used as a model to study the question of whether *in vitro* immune responses were true primary or early secondary responses.

GERMINAL CENTER

Federico Caligaris-Cappio, Cattedra di Immunologia Clinica, Dipartimento di Scienze Biomediche e Oncologia Umana, Università di Torino, Turin, Italy

In secondary lymphoid organs mature B lymphocytes tend to aggregate in nodular structures, the lymphoid follicles, that are located in well-defined areas such as the outer cortex of lymph nodes, the marginal zone of the spleen and the Peyer's patches, and play a central role in the secondary immune response to T cell-dependent antigens (Ags). Two different types of follicles exist. Primary follicles are spherical collections of small resting B lymphocytes that cluster around specialized Ag-presenting cells (follicular dendritic cells, FDCs) and are found in germ-free animals as well as in human fetal lymph nodes from the 16th gestational week onward. After Ag challenge, i.e. soon after birth, primary follicles evolve into secondary follicles through the progressive generation of a mitotically hyperactive population of B cells which form an area called the germinal center (GC) that is surrounded by a mantle or corona of small resting B lymphocytes. The GC provides the unique microenvironment of cells, adhesion structures and cytokines that ensure the proper balance between activation/proliferation and apoptotic death of newly generated Ag-specific B lymphocytes and lead to an antibody (Ab) response of optimal affinity.

Organization and cellular composition

GCs are placed eccentrically within secondary follicles and have a zonal structure (Figure 1). The upper pole of a GC possesses a prominent crescent-like cap of B mantle lymphocytes: this area is defined as the light zone because of the weak basophilia of the cells. At the opposite (lower or basal) pole, the B mantle may be reduced to a tiny rim of a few cells

encompassing an area of highly basophilic cells: the dark zone. The cellular organization of a GC is very composite: B, T and accessory cells have a specific distribution in the different zones of the GC.

Different populations of B lymphocytes form the major cellular component of a GC. According to the level of activation and differentiation, GC B cells have specific morphological, phenotypical and molecular features and occupy different areas, but, in spite of these differences, have two common features. First, they are unable to bind to postcapillary high endothelial venules (HEVs) and lack the normal migratory mechanism that most small lymphocytes possess. Second, they strongly express the adhesion molecules responsible for homotypic adhesion of lymphoid cells, CD11a/CD18 and their natural ligand ICAM 1 (CD54). These properties suggest that GC B cells behave as sessile elements and that Ag-recruited B lymphocytes become transiently segregated into lymphoid follicles in order to properly respond to the stimuli.

The dark zone is made up by centroblasts, a highly proliferating pool of large to medium-sized immature-looking cells with nucleoli and a sparse, intensely basophilic cytoplasm. Centroblasts are surface (s) immunoglobulin (Ig)D⁺, sIgM weakly positive and express major histocompatibility complex (MHC) class II molecules, CD19 and low amounts of CD10 and CD38. The light zone is chiefly made up by centrocytes, B lymphocytes of a more mature appearance with indented (cleaved) nuclei and a pale cytoplasm. Centrocytes are frequently IgG⁺ or IgA⁺, CD10⁺, CD38⁺. Further, a few immunoblasts and rare plasma cells are also observed within the light

zone. Finally, at the edge between the GC and the follicular mantle, cells coexpressing sIgM and the CD5 antigen (CD5⁺ B cells) are seen.

FDCs are a unique population of accessory cells found exclusively in follicles where they represent a numerically minor cell population (about 2%) that, nevertheless, plays a crucial role in the development of the GC, as follicles devoid of FDCs are never observed. Also, the nodular dissemination of malignant lymphocytes in GC malignancies is characterized by the clustering of monoclonal B lymphocytes around FDCs. FDCs form a dense meshwork of cytoplasmic processes around lymphoid cells which is most prominent in the light zone but extends its branches also amidst B lymphocytes in the corona. FDCs are unable to phagocytose and use their Fc and C3b receptors to fix and localize Ag-Ab complexes on their surface. These complexes provide a long-standing stimulation of GC B lymphocytes as Ag can be held on the FDC surface for more than a year.

Tingible body macrophages are large macrophages that owe their name to their ability to actively phagocytose apoptotic lymphoid cells (the 'tingible bodies' observed in their cytoplasm are apoptotic bodies) and, scattered among proliferating centroblasts, give the typical starry sky appearance to developing GCs. T cells represent about 5% of the GC cellular composition. Although infrequent, they appear to play a crucial role in the generation of the GC, as GCs are

virtually absent in congenitally athymic mice; this deficiency can be reversed by the transfer of T cells. T cells are very rare in the dark zone; they are more abundant in the light zone and are Ag specific. Nearly all GC T cells have the CD4⁺ helper phenotype, but exhibit some unusual features, such as the expression of CD57 and the inability to produce interleukin 2 (IL-2).

Function

GCs have a fivefold function that is based upon a coordinated process of proliferation/maturation/selection. First, they ensure the Ag-specific oligoclonal proliferation of B cells in the T cell-dependent secondary immune response. Although unexplained, an Ag-unrelated B cell proliferation also takes place in the GC, which might contribute to the overall amplification of the B cell pool. Second, GCs are the site of somatic hypermutations of immunoglobulin (Ig) V-region sequences that are required for the affinity maturation of Abs. It is still debated whether the T cell receptor may also occasionally mutate in GCs. Third, GCs are the site at which the isotype switch from IgM to IgG or IgA occurs. It is widely held that the high degree of apoptotic death observed within the GC, and witnessed by the starry sky histology, reflects the mortality of the cells with inadequacies in the switch and somatic hypermutation processes of Ig genes. Fourth, the GC microenviron-

ment generates B memory lymphocytes which can be recruited for a further round of proliferation/differentiation/selection by a forthcoming Ag challenge, and plasma cell precursors (plasmablasts). The precursors of plasma cells undergo their terminal differentiation into Ab-secreting cells at sites distant from the GC (medullary cords in lymph nodes, marginal zone in the spleen, lamina propria in the gut, bone marrow). This may be a security mechanism to prevent the developing immune response being prematurely shut off by the local buffering activity of high concentrations of Ab in direct contact with the triggering Ag. Finally, the GC microenvironment selects mature B cells by censoring (i.e. leading to the apoptotic death of) autoreactive cells.

Development

The primary response to T cell-dependent Ag occurs in the T cell areas of secondary lymphoid organs and generates Ag-specific B cells which migrate into follicles and give rise to GCs. Newly formed GCs are oligoclonal, as, on average, each mature GC is derived from the colonization of no more than 1–3 B cell blasts. Ag-specific immigrant B cells gather around the Ag-holding cytoplasmic protrusions of FDCs and are interspersed with Ag-specific T lymphocytes. Cycling B cells in the dark areas of the GC (centroblasts) undergo somatic mutations of the V_H and V_L genes that generate Ab of optimal affinity. Point mutations accumulate in the V_H and V_L genes independently of the V region utilized or of self specificity and are preferentially localized in the complementarity-determining region (CDR)-encoding segments. Centroblasts transform into noncycling centrocytes that migrate towards the light zone of the GC, switch their Ig phenotype under the control of cytokines and are eliminated by apoptosis, unless further stimulated by additional signals. The specific Ag interaction with surface Ig is the main signal that prevents apoptosis as it ensures the specificity of the selection process. Additional signals delivered through the interaction of B cell CD40 with its ligand (CD40L) also prevent apoptosis as assessed by *in vitro* tests and *in vivo* observations on patients with CD40L deficiency (X-linked hyper-IgM syndrome) or on CD40L knockout mice. CD40L is expressed primarily by T cells, again reaffirming the T cell dependence of GC formation. Other less well defined antiapoptotic signals are delivered by other cells (FDCs, macrophages or B cells themselves) through CD40–CD40L interactions (FDCs express CD40L) and the stimulation of CD20, CD21 and CD38 molecules. All these stimuli prevent apoptosis by inducing the expression of Bcl-2 protein, a potent

antidote to apoptosis. The majority of cells within the GC fail to express Bcl-2: proliferating centroblasts are Bcl-2 negative and only the centrocytes that have survived the whole molecular screening process of the GC become Bcl-2 positive and acquire the ability to survive. The GC-based screening program includes the prevention of autoimmune reactivity by inducing the apoptosis of self reacting B cells. Some censoring mechanisms that prevent the development of antiself reactions during the process of B cell selection in the GC have been partially elucidated. First, the exclusion of self Ag-binding B cells from the normal migration route into lymphoid follicles. Second, the exposure of self Ag-specific B cells to excess soluble Ag. Also, centrocytes exposed to CD40L upregulate the expression of Fas/CD95, a member of the tumor necrosis factor (TNF)-receptor (R) superfamily that transduces apoptotic signals to B cells upon interaction with activated T cells expressing CD95L. Thus, additional pathways to eliminate unwanted B cells may be controlled by T cells by means of the CD95/CD95L system.

Cytokines and the GC

A number of cytokines are involved in the generation of GCs: interferon γ (IFN γ) and IL-2 impede while IL-4 and IL-6 favor GC formation. IL-10 prevents the spontaneous death of GC B cells by induction of Bcl-2 protein. Further, it has recently been shown that GCs fail to develop in lymphotoxin- α or type I TNF-R-deficient mice. Likewise, the stimuli delivered by cytokines that induce the isotype switches have been partially elucidated. Activated B cells switch from IgM to IgG1 or IgG3 in the presence of IL-10, and to IgA1 or IgA2 in the presence of transforming growth factor β (TGF β). IL-4, especially in conjunction with IL-13, induces IgE and IgG4 production.

The fate of the GC

GCs are fluctuating structures which acquire their fully fledged zonal aspect through different steps. In the experimental animal, the first step is the appearance, 3–4 days after Ag injection, of foci of actively proliferating centroblasts within primary follicles. After a further 24 hours, tingible body macrophages become apparent and give the typical starry sky histological picture. This phase continues over a period of 1–3 weeks and is characterized by the striking proliferative activity of centroblasts that divide every 6–7 hours. About 50% of centroblasts are in the S phase of the cell cycle 30 minutes after a single injection of [3 H]thymidine. Mutations are introduced in a stepwise manner throughout this proliferative period

and this phase is followed by the progressive transformation of centroblasts into centrocytes that are selected on the basis of their ability to interact with the Ag held on the surface of FDCs. Some centrocytes may re-enter the centroblast pool and undergo another round of proliferation (and mutation), thereby explaining the rapidity of the occurrence of a high-affinity secondary Ab response. Little or no trafficking exists between GCs: therefore, clonal evolution proceeds independently within each GC, which autonomously provides the optimal microenvironment to the selected clones. Centrocytes either give rise to B memory cells or to plasma cell precursors (plasmablasts), which then migrate to other areas. The choice between differentiation into plasma cell precursors or memory cells is a finely tuned process controlled by different genes and cytokines whose molecular details are still largely undefined.

With time, GCs may either be potentiated by the influx of new antigenic waves, or disappear or develop into the so-called 'regressively transformed GCs' or 'progressively transformed GCs'. The regressively transformed GCs are observed after corticosteroid therapy when no lymphoid cells, but only hyalinized PAS⁺ (periodic acid-Schiff reaction¹) material can be seen within GCs. The progressively transformed GCs are follicles observed in nonspecific lymphadenitis when the border between the GC and B mantle cells becomes first indeterminate and finally totally lost, with the formation of nodules containing abundant numbers of lymphocytes.

GLUCOCORTICOIDS

Paul M Guyre and **Allan Munck**, Department of Physiology, Dartmouth Medical School, Hanover, New Hampshire, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The adrenal cortex produces two types of steroid hormones that are essential for life: glucocorticoids and mineralocorticoids. The outer zone of the cortex, the zona glomerulosa, produces the powerful mineralocorticoid aldosterone. The inner zones, the fasciculata and reticularis, produce the glucocorticoids and various androgens. Glucocorticoids act on almost all cells in the body, influencing a host of physiological processes including glucose metabolism, immune and inflammatory reactions, blood pressure regulation, and mental functions. They are essential at basal levels for maintenance of many homeostatic systems. Furthermore they are stress hormones, being secreted at higher than basal rates in response to stress and protecting the organism from stress.

Clinically, glucocorticoids are almost unique among hormones in that they are used for the treatment of a multitude of conditions apparently unrelated to hormone deficiency. Among these conditions are rheumatoid arthritis, asthma, allergy, autoimmune diseases, lymphocytic leukemias and lymphomas. Therapeutic doses used in such cases are often large enough to override normal physiological controls and functions of the glucocorticoids, producing unwanted side-effects.

Historical and physiological background

Thomas Addison reported in the mid-1800s on a series of patients who had succumbed to a disease – later named after him – associated with degeneration of the adrenal glands. Foreshadowing a relation between the adrenal cortex and the immune system, he noted that the blood of one patient ‘had a considerable excess of white corpuscles’. By the early 1900s patients with Addison’s disease, as well as adrenalectomized animals, were known to suffer from low blood glucose and salt loss. These effects were traced in the 1930s to two distinct hormones from the adrenal cortex, each essential for life: glucocorticoids, which influenced blood glucose; and mineralocorticoids, which regulated salt balance. The vital role of mineralocorticoids was well explained by their effects on salt balance, but that of glucocorticoids could not be accounted for by effects on glucose, and remained obscure for many years. By 1940 it was known that glucocorticoids exert numerous other actions, in particular on lymphoid

tissue: Addisonian patients and adrenalectomized rats had enlarged thymuses, and glucocorticoids caused atrophy of the thymus and other lymphoid organs.

Harvey Cushing in 1932 described a disease later ascribed to excessive secretion of glucocorticoids. Symptoms such as glucose intolerance, fat redistribution and heightened susceptibility to infection which accompany Cushing’s syndrome are nowadays most often encountered as undesirable side-effects of glucocorticoid therapy.

Around 1930 it became clear that there is an intimate relationship between glucocorticoids and stress. Stress from almost any source – cold, injury, infection, fright, and other challenges to homeostasis – stimulated glucocorticoid secretion. The resulting high levels of glucocorticoids protected against stress and sustained life, and for a long time were thought to somehow enhance the activity of normal defense mechanisms. A separate protective role for glucocorticoids emerged later from observations that adrenalectomized animals, which died if stressed, could survive moderate – though not severe – stress if maintained on basal levels of glucocorticoids. Such basal levels exert ‘permissive’ effects essential to maintain a wide range of homeostatic mechanisms, including blood pressure regulation and certain immune reactions.

The principal natural glucocorticoids are cortisol and corticosterone (**Figure 1**), the former predominating in humans and the latter in rodents. For many years cortisone, which was isolated in the 1940s, was thought to be the principal glucocorticoid, but it is now known to require conversion to cortisol for biological activity by reduction of the ketone group at carbon 11 to a hydroxyl group (**Figure 1**).

Until 1949 the main clinical use of glucocorticoids was for replacement therapy of patients with hormone deficiency. That year the biomedical world was electrified by the totally unexpected discovery that large doses of cortisone exerted powerful anti-inflammatory activity, dramatically alleviating the symptoms of rheumatoid arthritis. This development led to a spectacular rise in applications of glucocorticoids – the ‘miracle drugs’ of the 1950s – and set the stage for much of their current clinical use. Innumerable derivatives of the glucocorticoids were syntheses-

Figure 1 Structures of the natural glucocorticoids, cortisol and corticosterone, and of cortisone, an inactive metabolite derived from cortisol by oxidation of the 11-hydroxyl group.

ized in pursuit of compounds with reduced salt retention and other unwanted side-effects, a quest that yielded prednisolone, dexamethasone and other important steroids in current use (Figure 2).

The discovery of the anti-inflammatory effects also caused turmoil among adrenal physiologists, who were unable to reconcile the suppressive effects on inflammation with their assumption that stress-induced glucocorticoids stimulated defense mechanisms. Consequently they stigmatized the anti-inflammatory effects as pharmacological artifacts without physiological significance, leaving the major therapeutic applications of the glucocorticoids with no apparent physiological foundation. That paradoxical situation prevailed for over three decades. In recent years an alternative view of the protective role of glucocorticoids in stress that reconciles glucocorticoid physiology with therapy has gained strong experimental support. It proposes that in many circumstances high, stress-induced levels of glucocorticoids actually protect the organism from its own stress-activated defense mechanisms, suppressing those mechanisms to prevent them from overshooting and causing damage. This view places immunosuppressive, anti-inflammatory and other such actions at the center of glucocorticoid physiology.

Glucocorticoids can therefore be viewed as sustaining life through two different but related mechanisms: they 'permissively' activate some homeostatic defense mechanisms and, generally at higher levels, they prevent such mechanisms from overshooting. In the course of normal diurnal variation they probably exert both these influences to varying degrees; under stress, the second may predominate. Figure 3 illustrates qualitatively how activity of a defense mechanism might be influenced at various cortisol concentrations. Levels of free cortisol in humans vary diurnally over the lower range of the bell-shaped curve, rising in the morning to roughly the concentration for peak activity. Stress-induced levels can go well into the suppressive range.

Regulation of glucocorticoid secretion via the hypothalamo-pituitary-adrenal (HPA) axis began to be understood in the 1930s. ACTH (adrenocorticotrophic hormone) was identified as the anterior pituitary peptide that stimulates glucocorticoid secretion as well as growth of the inner zones of the adrenal cortex. Its secretion was eventually shown to be stimulated by the hypothalamic hormone CRH (corticotropin-releasing hormone) in conjunction with VP (vasopressin, also a hypothalamic hormone). Glucocorticoids in turn exert negative feedback on production of CRH, VP and ACTH, thus

Figure 2 Structures of the synthetic glucocorticoid analogs prednisolone and dexamethasone, and of the glucocorticoid (and progesterone) antagonist RU486.

Figure 3 Bell-shaped curve that illustrates schematically how the capacity of certain homeostatic defense mechanisms to respond to challenges is permissively enhanced by basal levels of glucocorticoids and suppressed by stress-induced levels.

regulating their own secretion. Stress signals override negative feedback control, and via the hypothalamus stimulate the HPA axis to produce stress-induced levels of glucocorticoids. A consequence of negative feedback regulation is that glucocorticoid therapy can cause atrophy of the HPA axis, leaving a patient without the capacity to respond to stress. Some of these relationships are shown in Figure 4, where some glucocorticoid effects on peripheral tissues are depicted as primary, being exerted directly through glucocorticoid receptors in the cells that are affected, and others as secondary to modulation – usually inhibition – of production or activity of cytokines,

inflammatory agents and other mediators. Recent studies strongly suggest that certain cytokines, such as interleukin 1 (IL-1), which are produced during immune responses, act on the hypothalamus to stimulate secretion of glucocorticoids. Glucocorticoids, in turn inhibit cytokines, forming a negative feedback loop that can regulate immune reactions.

Glucocorticoid receptors and molecular mechanisms

Glucocorticoid receptors were first identified in the 1960s in thymus cells. They have since been found

Figure 4 Feedback regulation of glucocorticoid secretion. See text for details.

in almost all cells, supporting the conclusion that almost all cells are targets for glucocorticoids. Like other members of the steroid and thyroid hormone receptor family, the type I (mineralocorticoid) and type II (glucocorticoid) adrenal steroid receptors are ligand-dependent transcription factors which act in the nucleus. Glucocorticoid receptors usually number from 1000 to 20 000 per cell. Before they are bound by hormone, the nonliganded glucocorticoid receptors (i.e. receptors without bound hormone) are seen mainly in the cytoplasm as large oligomers with HSP90 (90 kDa heat shock protein) and other heat shock proteins. When a glucocorticoid binds to its receptor, it forms a nonactivated hormone–receptor complex. Within seconds or minutes, the oligomer releases the heat shock proteins and is transformed to an activated hormone–receptor complex with high affinity for receptor-specific DNA-binding sites (hormone response elements or HREs) associated with hormone-regulated genes. Binding of glucocorticoid–receptor complexes as dimers to HREs alters transcription rates and levels of the mRNAs encoded by the glucocorticoid-responsive genes, eventually altering levels of the proteins that produce the hormone effects. This general scheme is illustrated in Figure 5.

A number of molecular mechanisms by which glucocorticoid receptors can modulate gene expression without necessarily binding to HREs have recently

been identified, and may underlie many immunosuppressive and anti-inflammatory actions. These include 1) blocking the transcription factor AP-1 from binding to its target genes, 2) binding to the transcription factor NF κ B, preventing it from binding to DNA, 3) increasing synthesis of I κ B α , an inhibitor which holds NF κ B in an inactive form in the cytoplasm, and 4) negatively regulating mRNA stability (e.g. for IL-1 and IL-6) by as yet unknown mechanisms.

In a surprising recent development, natural glucocorticoids have been shown to bind to type I receptors almost as strongly as aldosterone, the principal mineralocorticoid. Their affinity for mineralocorticoid receptors is, in fact, much higher than for glucocorticoid receptors. Since glucocorticoids are usually present in the body far in excess of aldosterone, the question arises as to how mineralocorticoid receptors can respond specifically to aldosterone. It turns out that mineralocorticoid target cells contain a unique enzyme, 11 β -hydroxysteroid dehydrogenase, which ‘protects’ mineralocorticoid receptors by rapidly inactivating glucocorticoids, converting cortisol, for example, to cortisone. The full physiologic implications of glucocorticoids binding to type I receptors is still being explored, but already it seems likely that certain actions of glucocorticoids in the brain are mediated through ‘unprotected’ mineralocorticoid receptors. What role

Figure 5 Receptor-mediated genomic mechanisms of action of steroid hormones. The hormone, H, is assumed to diffuse freely into the cell, where it binds reversibly to the nonliganded receptor R to form a nonactivated hormone–receptor complex HR. HR is rapidly activated, with dissociation of two HSP90 (90 kDa heat shock protein) subunits and other heat shock proteins, to give the activated complex HR' that can bind to nuclear structures to form nuclear complexes HR'n. Some of the HR'n associate with TFs (transcription factors such as AP-1 or NF κ B) and bind as dimers to hormone response elements (HREs) in the promoter regions of hormone-regulated genes. Stimulation or inhibition of the rate of transcription of those genes alters the levels of the mRNAs and proteins for which they encode. The proteins produce the hormone effects.

mineralocorticoid receptors may play in glucocorticoid actions on the immune system remains to be elucidated.

Anti-inflammatory and immunosuppressive effects

Suppression of inflammatory and immune reactions and treatment of cancers of the lymphoid system are among the major applications of glucocorticoids. As noted above, despite early assumptions that such 'pharmacological' effects had no physiological basis, it is now clear that they are as physiological as are the effects on glucose metabolism. For example, induction of adrenal insufficiency in experimental animals (by adrenalectomy or administration of the glucocorticoid antagonist RU486) enhances inflammatory and immune reactions, showing that these reactions are physiologically regulated by endogenous glucocorticoids. Studies by Sternberg and coworkers also strongly suggest that dysregulation of the HPA axis can result in autoimmunity.

Anti-inflammatory and immunosuppressive actions of glucocorticoids are now known to be closely related, affecting nearly all cells that participate in immunity and inflammation and sharing fundamental cellular and molecular mechanisms that are under glucocorticoid influence. Glucocorticoids dramatically alter the distribution of leukocytes, markedly decreasing blood counts of lymphocytes, monocytes, eosinophils and basophils within 1–3 h of glucocorticoid administration. Recent work has shown that changes in blood leukocyte distribution result from glucocorticoid interaction with the type II adrenal steroid receptor. While neutrophil counts rise in the blood, glucocorticoids decrease the accumulation of leukocytes at inflammatory sites. Glucocorticoids also kill lymphocytes, largely by the initiation of apoptosis, a striking effect that is applied in the treatment of lymphocytic leukemias and lymphomas.

Numerous reactions that are fundamental to immunity – antigen-induced T and B cell proliferation, early B cell differentiation, antigen presentation, NK activity, differentiation and activation of macrophages – are suppressed by glucocorticoids. Although some of these are probably direct effects on the target cell being measured, others certainly involve indirect effects resulting from glucocorticoid regulation of intermediary molecules. In the past 20 years, the ability of glucocorticoids to inhibit the production of various inflammatory enzymes and cytokines, by mechanisms such as those outlined above, began to be recognized. **Table 1** contains a partial list of mediators which are obligatory components of immune and inflammatory reactions

Table 1 Glucocorticoid regulation of mediators involved in immunity and inflammation

<i>Increased mRNA and/or protein</i>
Annexin I (lipocortin-1)
β_2 -Adrenergic receptor
Macrophage inhibitory factor
<i>Decreased mRNA and/or protein</i>
Interleukins 1, 2, 3, 4, 5, 6, 8, 11, 12, 13 (immune cytokines)
TNF α , GM-CSF, RANTES, MIP-1 α , SCF (inflammatory cytokines/chemokines)
iNOS (inducible nitric oxide synthetase)
COX-2 (inducible cyclooxygenase)
cPLA $_2$ (inducible phospholipase)
Endothelin-1 (bronchoconstrictor)
ICAM-1, VCAM-1 (adhesion molecules)
Collagenase, elastase, plasminogen activator (proteases)
Bradykinin, serotonin, histamine (inflammatory mediators)

and whose production is inhibited by glucocorticoids. Glucocorticoids also inhibit some effects of these mediators, such as responses of lymphocytes to IL-2 and of eosinophils to IL-3, IL-5, GM-CSF and IFN γ . By blocking communication via cytokines, glucocorticoids cut off signals required for clonal expansion and differentiation of antigen-specific T and B cells, as well as signals which activate effector functions that participate in inflammatory reactions. It seems likely, therefore, that a principal mechanism through which glucocorticoids control immune and inflammatory reactions is by suppressing cytokines and other mediators.

The complexity of the interplay between glucocorticoids and inflammatory mediators is evidenced by the increased expression of certain cytokine receptors in response to glucocorticoids, and probably by altered expression of glucocorticoid receptors induced by some cytokines. How might such effects fit with the models presented in **Figures 3** and **4**? Basal levels of glucocorticoid, and possibly the surge which occurs early in an immune response, may initially enhance the actions of cytokines by increasing expression of cytokine receptors. As cytokine concentrations rise, they act on the HPA to stimulate even higher levels of glucocorticoids which restrain further cytokine production unless very strong inflammatory signals persist. Normally, elimination of the antigen and resolution of the inflammation allows cytokine production to cease so that both cytokines and glucocorticoids return to basal levels. However, sustained inflammation with continued high levels of cytokines can persist in spite of high levels of glucocorticoid. This outcome might result in part from cytokine-induced reduction in glucocorticoid receptor expression, a mechanism postulated by some to contribute to steroid-resistant asthma.

GLYCOSYLATION OF IMMUNE SYSTEM MOLECULES

Raj B Parekh, Oxford Glycosystems, Abingdon, UK

The secreted and membrane-associated polypeptides of higher organisms are subject to a variety of post-translational modifications involving carbohydrate moieties. Of these, the most common is *N*-glycosylation, in which an oligosaccharide is attached to the Asn residue of an Asn-X-Ser(Thr) by an *N*-glycosidic bond, and *O*-glycosylation in which an oligosaccharide is attached to a serine or threonine residue through an *O*-glycosidic bond. Both *N*- and *O*-linked oligosaccharides are branched, structurally complex molecules possessing secondary and tertiary structure. An individual *N*-glycosylation site generally does not contain a single oligosaccharide structure, but rather a *conserved population* of oligosaccharide structures. This phenomenon is usually referred to as microheterogeneity, and, since most glycoproteins have several *N*-glycosylation sites, it means that a polypeptide is diversified by glycosylation into a set of *glycoforms*, which differ with respect to the structure and location of oligosaccharides on a common amino acid sequence. That is, a

glycoprotein really exists as a set of discrete glycoforms, and it is this set of glycoforms which at any developmental stage constitutes the final expression of that polypeptide by the cellular population. This structural diversification in some cases at least (e.g. immunoglobulin G (IgG)) correlates with functional diversification, and the activity of a glycoprotein may really be a weighted average of the activity of each set of glycoforms. Further, glycosylation is cell type specific. A single polypeptide expressed in two different cell types (or tissues) of the same species is *N*-glycosylated differently. That is, cells have a unique *glycotype*. The final glycosylation of a polypeptide reflects numerous intracellular events, and changes in glycosylation are proving to be an increasingly valuable probe for cellular function and dysfunction.

The structural and functional consequences of polypeptide glycosylation in general are only slowly being elucidated, largely due to the difficulties in performing accurate structural analysis on the population of complex, branched oligosaccharides as-

sociated with a polypeptide. Nevertheless, it is emerging that oligosaccharides, being intrinsic and inseparable components of glycoproteins, modulate to a greater or lesser extent almost every aspect of glycoprotein function. For example, physicochemical properties, immunogenicity, and antigenicity, as well as individual biological functions, are all influenced by oligosaccharide.

Many of the molecules involved in the initiation, execution, and control of immunological processes are glycosylated, some very heavily. For example, most members of the immunoglobulin superfamily carry *N*-linked oligosaccharides as do many cytokines and most leukocyte cell surface proteins. IgG has been studied the most extensively with respect to the structure and function of oligosaccharides attached to molecules involved in immune responses and will therefore form the focus of this article.

Glycosylation of IgG

All normal serum immunoglobulins carry *N*-linked oligosaccharides. This is true for all classes and subclasses in every species studied to date. These *N*-linked oligosaccharides are located at conserved *N*-glycosylation sites on the Fc (the precise position depending on class), and at nonconserved sites on the Fab. In addition, immunoglobulins from certain species carry *O*-linked oligosaccharides. For example, rabbit IgG carries one or two (depending on allotype) *O*-linked oligosaccharides in the hinge region, but human serum IgG invariably lacks *O*-linked oligosaccharides. In the case of IgG, particularly detailed structural analysis of glycosylation has been performed.

Human serum IgG carries, on average, 2.8 *N*-linked oligosaccharides. Of these, 2.0 are invariably located in the C_H2 domain at the conserved *N*-glycosylation site of Asn297 (Figure 1). The additional oligosaccharides are found attached to the hypervariable regions of the Fab, and their frequency, location and incidence appears to depend predominantly on the generation of an Asn-X-Ser/Thr *N*-glycosylation sequon during formation of the immunoglobulin repertoire. Isolation, fractionation and structural analysis on the oligosaccharides of IgG, and its Fab and Fc fragments, has shown that 31 different complex-type oligosaccharides are associated with total human serum IgG. These structures are nonrandomly distributed between Fab and Fc. Those oligosaccharides on the Fab are characterized by a high incidence of sialylated structures, and of 'cores' carrying a 'bisecting' GlcNAc (Figure 1). The Fc oligosaccharides are characterized by a low incidence of sialylated oligosaccharides and of 'bisecting' GlcNAc

in the cores, and by the absence of galactose on the α 1-3 arm of at least one oligosaccharide chain in the Fc. The large number of different oligosaccharides associated with IgG is not principally due to the analysis of a polyclonal population, since monoclonal antibodies in general show a heterogeneity of glycosylation similar to that found in the total serum IgG of the corresponding species. Further, the pattern of *N*-glycosylation of serum IgG is broadly similar between different species. In general, the oligosaccharide structures on any IgG can be accommodated within the same set of 31 oligosaccharides found on human IgG. Only the relative incidence of individual structures varies between species. Crystallographic studies on IgG and Fc fragments suggest an important structural role for the Fc oligosaccharides (Figure 1), consistent with this degree of conservation. The two oligosaccharides in the Fc engage in both protein-oligosaccharide and oligosaccharide-oligosaccharide interactions. These interactions appear to fill the interstitial region between the C_H2 domains, keep the two domains apart and maintain the stable and relatively inflexible conformation characteristic of Fc. A particularly curious feature of IgG glycosylation is the variation in the structure of oligosaccharides with age. In a study of normal healthy individuals varying in age from 1 to 70 years, the relative incidence of oligosaccharides totally devoid of outer-arm galactose (i.e. agalactosyl structures) was found to vary continuously with age in a parabolic fashion, with the minimum incidence of agalactosyl structures occurring at about 25 years of age, irrespective of sex. This age-related molecular parameter is so far unique in varying continuously in the normal population, and raises the possibility that those age-related variations in immunological competence which are also parabolic, may reflect an underlying change in glycosylation.

Functional consequences of IgG glycosylation

The oligosaccharides of the Fc do not appear to be involved in binding of antigen, protein A, or recognition by rheumatoid factor. This has been shown by several authors who have compared aglycosyl IgG produced by culturing cells in the presence of tunicamycin, with native IgG. Proteolytic susceptibility and those interactions between IgG and C1q or cellular-bound receptors are, however, critically affected by Fc oligosaccharides. For example, binding to monocyte and macrophage Fc receptors, induction of cellular toxicity, rapid clearance of immune complexes from serum, and feedback immunosuppression are all severely reduced in agly-

Figure 1 (A) A schematic representation of an IgG molecule indicating the positions of conserved *N*-glycosylation sites (at Asn297 in the C_H2 domains), and nonconserved *N*-glycosylation sites (in the hypervariable regions (dotted) of the Fab). The relative size of an immunoglobulin domain and a fully extended *N*-linked biantennary complex oligosaccharide are similar. Complex-type oligosaccharides present on IgG can be subdivided into an outer-arm region (a, a', b, b', c, c'), and the core, which is composed of a trimannosyl unit (d, d', e) and a *N,N'*-diacetylchitobiosyl unit (f,g). The 'bisect' GlcNAc (residue i) is linked $\beta(1-4)$ and the fucose (residue h) is linked $\alpha(1-6)$. The arrow between residues e and f indicates the site of interaction between the two oligosaccharides in B and C. (B) Refined structure at 2.80 Å of rabbit Fc fragment. The two carbohydrate chains, each attached at Asn297, differ in conformation, may also differ in sequence and bridge the C_H2 domains. The $\alpha(1-3)$ arm of the chain (left side) is always devoid of galactose and interacts through its $\beta(1-2)$ -linked GlcNAc residue (c) with the Man $\beta(1-4)$ GlcNAc segment of the opposing (right side) oligosaccharide chain (see A). The $\alpha(1-3)$ arm of the right chain extends outwards between the domains with no apparent steric constraints on its length. A Neu5Ac unit (a') is shown on one $\alpha(1-6)$ arm only (left). (C) Fragment containing oligosaccharides devoid of galactose and sialic acid on each of the $\alpha(1-6)$ arms. Since these residues in normal IgG are in contact with the surface of the protein (see B), their absence vacates oligosaccharide-binding sites in IgG from arthritic patients, and could make IgG 'sticky' by creating a lectin-like activity.

cosyl IgG. Further, serial lectin chromatography on total serum IgG has shown that there normally exists within serum IgG a *range of affinities* for monocyte Fc receptors, and this range is independent of subclass or antigenic specificity but correlates with Fc

N-glycosylation. That is, both the presence and nature of Fc glycosylation affect its interaction with the monocyte Fc receptor, and the naturally occurring glycoforms of IgG differ in this respect.

While interaction with cell surface receptors is

clearly sensitive to Fc N-glycosylation, Fab N-glycosylation appears to exert more influence on solubility and aggregation phenomena. Naturally occurring univalent (and therefore nonprecipitating) antibodies are formed by N-glycosylation of only one of the Fab arms (asymmetric glycosylation). Apparently, the presence of an N-linked oligosaccharide at certain positions of certain Fab moieties leads to a marked reduction in affinity for antigen at that Fab. Enzymatic removal of such an oligosaccharide restores the natural antigen affinity and renders the molecule bivalent. Interestingly, the oligosaccharide rendering some IgG molecules univalent almost invariably carries nonreducing terminal mannose residue(s), suggesting that such antibodies, though univalent, may activate the alternative complement pathway through interaction with serum mannan binding-lectin. The aggregation of IgG into IgG complexes is in some cases also Fab oligosaccharide-related. The cryoglobulin and cold agglutinin properties of some IgM and IgG monoclonal antibodies are dependent on the presence of certain Fab oligosaccharides.

A study of IgG N-glycosylation has provided new insights into the etiopathology of certain human diseases, particularly rheumatoid arthritis (RA), tuberculosis (TB), and Crohns disease. When the N-linked oligosaccharides of total serum IgG from normal individuals and patients suffering from active RA are compared, it is found that IgG from RA patients has a dramatically decreased incidence of structures terminating in outer-arm galactose, and therefore a corresponding increase in structures terminating with outer-arm N-acetylglucosamine ($P < 0.001$ by analysis of covariance). In effect, IgG totally lacking galactose [IgG(0)] is markedly raised. This change is also found in juvenile-onset RA (irrespective of the precise mode of onset), TB, Crohns disease, and systemic lupus erythematosus with Sjögrens. It is *not* found in myositis, scleroderma, psoriatic arthropathy, ankylosing spondylitis, osteoarthritis, reactive arthritis, sarcoidosis, multiple sclerosis, *Klebsiella* infection, or a variety of viral infections such as rubella and mumps. The change in galactosylation is therefore not a correlate of chronic inflammation, autoimmune rheumatic diseases, arthropathies, or infectious diseases, but is highly specific to adult and juvenile-onset RA, TB and Crohn's disease, and furthermore, the extent of the reduction in galactosylation closely parallels disease activity. Recent *in vivo* studies by Rademacher and

colleagues have demonstrated that IgG(0) is pathogenic in the collagen-induced arthritis model in DBA/1 strain mice.

GOODPASTURE'S SYNDROME

Juan Saus, Instituto de Investigaciones Citológicas de la Fundación Valenciana de Investigaciones Biomédicas and Departamento de Bioquímica y Biología Molecular de la Universitat de Valencia, Valencia, Spain

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Since Ernest Goodpasture described the coexistence of hemoptysis and progressive renal failure in a young man after an episode of influenza in 1919, important advances have been made in our understanding of this unusual and, so far, exclusively human disease. Milestones have been the finding that the major pathogenic event is the linear deposition of circulating immunoglobulin G (IgG), the GP (Goodpasture) antibodies, along glomerular and alveolar basement membranes and the identification of the GP antigen as the C-terminal region of the $\alpha 3$ chain of basement membrane collagen IV.

Today the definitive diagnosis of GP syndrome is based on the detection of circulating antibodies against $\alpha 3(\text{IV})\text{NC1}$ in patients with renal-pulmonary involvement. Evidence suggests that the unique manner in which these high-affinity antibodies bind to the glomerular basement membrane efficiently interferes with plasma filtration. Restricted regions at both ends of the antigen are involved in antibody binding and in the formation of the GP epitope. Exclusively in humans, the N-terminal portion of this epitope can be phosphorylated and exists in multiple alternative antigen-related products that vary in their ability to be phosphorylated. In predisposed individuals, disturbance of these or other human-restricted processes may cause changes in the GP antigen peptide presentation and thereby initiate the autoimmune response.

The Goodpasture antigen and the pathogenic epitope

Basement membranes are specialized structures of the extracellular matrix found at the boundaries between cells and connective tissues. They play important roles in tissue and organ development and repair; in guiding cell migration and in signaling differentiation; and, in certain locations, such as in glomerulus, choroid plexus and alveolus, basement membranes control fluid exchange between the compartments they separate. In these three locations, the membrane appears to have arisen by the fusion of an endothelial and epithelial membrane. Interestingly these double-width basement membranes have been implicated in the autoimmune attack carried out by the GP antibodies (Figure 1).

A network of interacting collagen IV molecules

Figure 1 Principal organs affected in Goodpasture's syndrome.

(Figures 2 and 3) in close association with laminin (not shown) contribute respectively the structural strength and the adhesiveness required to build a typical basement membrane. The proportion and subunit composition of some of the constituents, including collagen IV, greatly varies among basement membranes.

Collagen IV is a nonfibrillar collagen exclusively found in basement membranes, where it is also the major structural component. As in other collagens, it is a triple helix composed of three intertwined α chains (Figures 2 and 3). So far, six different but related α chains, $\alpha 1(\text{IV})$ – $\alpha 6(\text{IV})$, have been characterized in collagen IV. The presence of noncollagenous sequences along each individual $\alpha(\text{IV})$ chain causes imperfections in the resulting triple helix that prevent its molecular assembly into fibrils. Among

Figure 2 Diagram representing the localization and structural identification of the Goodpasture antigen from organ level to molecular level: (A) Cross-section of the kidney. (B) The functional unit of the kidney, the nephron. (C) The filtration unit of the nephron, the glomerulus. The blood enters the capillary tuft and the filtrate is forced out of the capillaries over the glomerular basement membrane into the surrounding Bowman's capsule. (D) Micrograph of the glomerular basement membrane (B) located between the fenestrated (f) endothelium (En) on the capillary (c) side and the epithelial foot processes (fp) on the urinary (U) side (Bowman's space). (E) Schematic drawing representing the collagen IV network of a basement membrane. Four collagen molecules are cross-linked through their N-terminal domains (7S) and two through their C-terminal domain (NC1). (F) Enlargement of a schematic collagen IV molecule in which the principal domains are indicated. (Figure courtesy of Charlotte Brunmark, originally presented in her doctoral dissertation 'Type IV collagen and renal disease'.)

the noncollagenous sequences, the C-terminal region or NC1 domain is the largest and conforms to a highly folded disulfide-rich region that guides, among other processes, the triple helix formation. In the basement membrane, two molecules of collagen IV interact through their NC1 domains to yield a

hexameric structure that can be released from the corresponding network by collagenase digestion (Figure 3). This hexamer is compacted by noncovalent forces and by disulfide bonds and yields monomer and disulfide-related dimers under denaturing conditions. The GP epitope is hidden within the iso-

Figure 3 Representation of a hypothetical collagen IV network in which the six characterized $\alpha(\text{IV})$ chains are assembled into three types of collagen IV molecules ($(\alpha 1)_2\alpha 2$; $(\alpha 3)_2\alpha 4$; $(\alpha 5)_2\alpha 6$) and interactions through the NC1 domains are restricted to homologous molecules. There is evidence for the existence of $(\alpha 1)_2\alpha 2$ and $(\alpha 3)_2\alpha 4$ but not for $(\alpha 5)_2\alpha 6$. Other collagen IV compositions and interactions expected to occur are not represented in the drawing for simplicity. Bacterial collagenase digestion of the collagen IV network releases the hexameric NC1 domain that yields monomer and related dimers upon dissociation. The antigenic determinants recognized by the GP antibodies are hidden within the isolated hexamer and only exist in the $\alpha 3(\text{IV})\text{NC1}$ -containing material. At the lower right side, the hexamer was analyzed by denaturing electrophoresis and transferred to a nitrocellulose membrane. The membrane was sliced in two and the individual pieces blotted with Goodpasture serum (left) or with monoclonal antibodies recognizing the N-terminal region of the human $\alpha 3(\text{IV})\text{NC1}$ (right). The undistinguishable reactive patterns in both monomer (M) and dimer (D) regions localizes the Goodpasture antigen to the $\alpha 3(\text{IV})\text{NC1}$ domain.

lated hexamer since the unfolding of the hexamer is required for full GP antibody recognition (Figure 3).

The expression of each individual chain varies greatly among tissues with a more restricted distribution for the $\alpha 3(\text{IV})$ – $\alpha 6(\text{IV})$ chains. In the glomeruli, the $\alpha 3(\text{IV})$ – $\alpha 5(\text{IV})$ chains are coordinately

expressed and it appears that these three chains assemble into a collagen IV network different but connected to the more classic and ubiquitous one composed of the $\alpha 1(\text{IV})$ – $\alpha 2(\text{IV})$ chains. Typically in the Alport syndrome, a condition arising from mutations in the $\alpha 3(\text{IV})$, $\alpha 4(\text{IV})$ or $\alpha 5(\text{IV})$ genes, the

glomerulus does not express the $\alpha 3(\text{IV})$ - $\alpha 5(\text{IV})$ chains. In Alport patients, the glomerular basement membrane displays a split structural appearance caused by the defective fusion of the endothelial and epithelial basement membranes, resulting in a severe impairment of the plasma filtration. This pathology reveals that the $\alpha 3(\text{IV})$ - $\alpha 5(\text{IV})$ network cements the double-width basement membrane and is a critical structural requirement for the glomerular filtration. This structural-functional relationship is further supported by the renal failure that results from the particular binding of antibodies to the C-terminal domain of $\alpha 3(\text{IV})$ in GP patients.

Collagenase digestion of the human $\alpha 3(\text{IV})$ chain releases the GP antigen, a 244-residue polypeptide consisting of a short nondigested collagenous sequence at the amino end followed by the NC1 domain (Figure 4). The molecular cloning of the different human $\alpha(\text{IV})$ chains and that of $\alpha 3(\text{IV})$ from other species has allowed comparative studies that have identified the pathogenic epitope and certain biological features unique to the human antigen. The GP epitope is discontinuous, disulfide-dependent and involves at least both ends of the antigen (Figure 4). In humans, the amino-side of the GP epitope is phosphorylated by type A protein kinases and antigen-

related products produced by alternative exon splicing regulate the process. These alternative products share the phosphorylatable amino-side of the epitope with the primary antigen and diverge from it at the C-terminal region. The shorter, divergent C-terminal regions do not contain the structural requirements to build a classic NC1 domain and therefore are not expected to guide triple helix formation. However, they do confer a distinct susceptibility to phosphorylation to the common N-terminal region.

The Goodpasture antibodies and the antigen-antibody reaction

The detailed characterization of the autoantibodies present in patients with renal-pulmonary syndromes is important since treatment and prognosis vary greatly depending upon antibody specificities. The poor prognosis associated with the presence of circulating GP antibodies justifies the 'toxic' quality by which they are known. The GP antigen is especially immunopathogenic and the specific way in which GP antibodies bind is critical in determining the severity of the resulting nephritis. This is supported by the fact that the development of experimental GP syndrome requires the administration of dimeric

Figure 4 (A) Schematic representation of the 244 residues (circles) of the collagenase digestion product of the human $\alpha 3(\text{IV})$, the Goodpasture antigen, according to a previously reported model for the NC1 domain of a single $\alpha(\text{IV})$ chain (Siebold B. *et al* (1988) *European Journal of Biochemistry* **176**: 617-624; Kalluri *et al* (1991) *Journal of Biological Chemistry* **266**: 24018-24024). The disulfide bonds are represented by short black bars and the residues involved in the Goodpasture epitope are filled in dark. The collagenase cleavage site and the triple helix-NC1 junction are indicated. (B) Sequence comparison between the amino (NH₂) or carboxyl (COOH) sides of the Goodpasture epitope and the homologous regions of the indicated $\alpha(\text{IV})$ chains. The exclusive phosphorylation site in humans at the amino-side is indicated (P). The arrowhead and the bent arrow respectively indicate the beginning of the GP antigen (collagenase cleavage site) and the NC1 domain in the human $\alpha 3(\text{IV})$ sequence. Residues are represented in one-letter codes. The points and letters respectively indicate the identical and the divergent residues in the indicated collagen IV chains when compared to the human $\alpha 3(\text{IV})$ sequence.

$\alpha 3(\text{IV})\text{NC1}$ domain while immunization with other dimeric $\alpha(\text{IV})\text{NC1}$ domains also results in autoantibody production but not in evident disease. Furthermore, the administration of the $\alpha 3(\text{IV})\text{NC1}$ domain as part of the hexamer also fails to provoke the experimental syndrome although the animals display high titers of $\alpha 3(\text{IV})\text{NC1}$ autoantibodies.

Therefore, only the specific recognition of the GP antigen by GP antibodies appears to cause GP syndrome and neither the presence of other non-GP anti- $\alpha 3(\text{IV})\text{NC1}$ or antibodies against the other NC1 domains can cause the disease. Consistently, normal human sera contain high titers of IgM and IgG antibodies that bind the antigen in a nonpathogenic fashion; and individuals with high titers of antibodies directed against the more abundant NC1 domain of the $\alpha 1(\text{IV})$ chain do not develop a rapidly progressive glomerulonephritis.

It seems likely that the unique binding of GP antibodies to the $\alpha 3(\text{IV})\text{NC1}$ domain not only causes a general inflammatory response but also specifically interferes with critical molecular interactions required for plasma filtration.

Pathogenesis

Upper respiratory infection, flu-like illness and inhalation of hydrocarbon solvents, chlorine gas or hard metal dust have been implicated as triggering events of the GP syndrome. However the precise molecular mechanism by which these triggers initiate autoantibody production is unknown. Evidence concerning the participation of T cells in the immuno-

pathogenic response also is indirect and circumstantial. However, mononuclear interstitial infiltrate comprised mainly of CD4^+ helper T cells is consistently found in the affected tissues; and the major immunoglobulin subclass to which GP antibodies belong (IgG1) also suggests T cell-mediated autoantibody production.

As stated previously, normal human sera contain high levels of IgM and IgG that specifically recognize the GP antigen. Interestingly, these nonpathogenic autoantibodies are significantly reduced in some GP patients. The coincidence of this up- and downregulation of autoantibody production suggests that the bulk of the B cell clones involved in both natural and pathogenic autoreactivity may be the same. The repetitive presence of the GP antigen along the basement membrane collagen IV network and the existence of these 'natural antibodies' also suggest that these B cells are normally being stimulated in a T-independent fashion (Figure 5). During pathogenesis, a T-dependent stimulation of these same B cells may cause an isotype switch to IgG-producing cells. Subsequently, somatic mutations in the class-switched B cells along with persistent and efficient antigen stimulation could lead to the production of the high-affinity GP antibodies. Efficient antigen stimulation appears to be of pathogenic relevance since effective immunization of experimental animals requires the administration of an accessible dimeric form of the antigen.

It is accepted that self-tolerance is mainly achieved by downregulating autoreactive helper T cells. A consequence of bypassing this control would be the

Figure 5 A hypothetical model for the autoimmune response in Goodpasture's syndrome. Soluble antigenic products are recognized by silent or T-independently induced B cells whose T-dependent induction cannot occur because the cognate T helper cells are tolerized ($t\text{-T}_{\text{H}}$). A triggering event may generate modified antigenic products that still are recognized by the B cells. In certain predisposed individuals, however, the modified products are distinctly processed and presented, and thereby bypass the tolerized T helper cells to initiate a T-dependent pathogenic response mediated by nontolerized T cells (nt-T_{H}).

induction of autoreactive cells leading to autoimmunity. In the present case, silent or T-independently stimulated autoreactive B clones could also be the target of a more solubilized form of antigenic products. Yet the corresponding T-dependent induction would not occur due to the presence of tolerized T helper cells. In certain genetically predisposed individuals, however, a triggering event causing antigen modifications may result in the presentation of 'new' peptides that bypass the tolerized T cells and thereby initiate a T-dependent autoimmune response (Figure 5).

In such an induction mechanism, the removal of altered antigen would terminate the immunopathological response and relapses would require a new effective trigger. This appears to be the case in the GP syndrome since kidney removal improves lung manifestations in some patients, and relapses are rare and related to re-exposure to a triggering agent. Furthermore, effective autoantibody removal from patient plasma commonly results in a virtual arrest of the autoimmune process indicating that the production of the pathogenic antibody is a temporally limited event.

Phosphorylation of certain serines by type A protein kinases and alternative splicing of the GP antigen are connected phenomena found exclusively in the human antigen but not in other species or in other human α (IV) chains. Both type A protein kinase and antigen phosphorylation have been independently implicated in the development of other autoimmune responses. Phosphorylation of specific serines modifies intracellular proteolytic processing of other proteins, suggesting that alterations in antigen phosphorylation can affect peptide presentation. The involvement of these or other unique biological processes yet to be discovered in the GP syndrome pathogenesis may explain why the natural disease is not described in other mammals, why other NC1 domains are not immunopathogenic and why this disease is so rare and with such a strong linkage to a particular presenting MHC haplotype (HLA-DR5).

GRAFT REJECTION

Margaret J Dallman, Department of Biology, Imperial College of Science Technology and Medicine, London, UK

Organ transplantation is currently the best clinical option for patients with end-stage renal failure, and indeed the only option for patients with failure of organs such as liver and heart. Although the survival rate for transplants (e.g. 1 year transplant survival for first cadaveric kidney transplants in the UK is ~80–85%) is now very high, one continuing problem with organ transplantation is that of graft rejection. In the 1940s, Medawar and his colleagues firmly established that graft rejection involved an immune response against the foreign antigens carried on tissues. A very large amount of work subsequently carried out in this area suggests that most facets of the immune system can be involved in the tissue destruction that results in graft rejection. Experimental models of transplantation continue to be of interest, not only to examine *in vivo* immune responses to alloantigens, but also to dissect the mechanisms of peripheral tolerance. The eventual goal of the latter work is to develop strategies to achieve graft-specific immunoregulation or tolerance in clinical transplantation in order that we may dispense with the nonspecific drugs that are currently used to prevent graft rejection.

Graft rejection may be divided into afferent and efferent phases – in the former the immune system becomes alerted to the presence of the foreign tissue, and in the latter the immune system destroys the graft.

Afferent phase

Antigens

It is the histocompatibility antigens present on cells of the transplant that activate the immune system of the host. Proteins encoded within the major histocompatibility complex (MHC) produce the most vigorous immune response, which, if left unchecked, will almost invariably lead to complete destruction of the graft. However, the minor histocompatibility antigens may also lead to graft rejection. Indeed,

multiple minor histocompatibility differences may lead to rejection of solid organ grafts as rapidly as that seen with MHC differences, and in bone marrow transplantation a single minor histocompatibility difference may lead to lethal graft-versus-host disease. Of the MHC antigens, class I antigens are found on probably all nucleated cells, but with a variable level. By contrast, class II antigens have a rather limited distribution on normal cells, their expression being restricted to B cells, some endothelial and epithelial cells, and cells of the dendritic cell lineage. The level of expression of both class I and class II antigens may be upregulated, and indeed class II-negative cells may be induced to express these antigens, *de novo*, in the presence of cytokines such as interferon γ (IFN γ) and tumor necrosis factor α (TNF α). Both class I and class II antigens become strongly upregulated on most cells of an organ transplant during graft rejection.

Differences of single class I or class II antigens may result in graft rejection, although the kinetics of rejection may vary with the incompatibility. The very great polymorphism of the MHC antigens means that it is usually only possible to transplant fully MHC-compatible grafts between siblings. Even then, minor antigen differences may occur. Indeed, it is only possible to graft tissue which is matched for both major and minor histocompatibility antigens between monozygotic twins. Thus, immunosuppression is always required in clinical transplantation and, even so, rejection episodes occur in many patients.

MHC antigens can be recognized either as intact proteins on the surface of the donor antigen-presenting cells (direct presentation) or as processed fragments in association with recipient MHC (indirect presentation). It is suggested that direct presentation is responsible for acute rejection, while indirect presentation may lead to the more insidious changes associated with chronic rejection.

Mice with disrupted expression of both β_2 -

microglobulin (class I^{-/-} mice) and class II genes (class II^{-/-} mice) have been generated and used as either donor or recipient of transplants. In many such experiments, a lack of class I or class II antigens alone on donor tissue has little effect on graft survival; however, in other experiments graft survival may be prolonged or permanent when donor tissue lacks either class I or class II or both class I and II antigens. Certainly, different results are obtained when different types of grafts are used, but the interpretation of apparently straightforward experiments is confounded not only by unusual features of the immune systems of these knockout mice but also by the suggestion that grafts from class I^{-/-} mice may be reconstituted in their expression of class I by serum β_2 -microglobulin in the recipient.

Recipients lacking class I or II antigens are severely depleted of CD8⁺ or CD4⁺ cells, respectively. Different workers obtain distinct results using such recipients, which is perhaps not surprising given the results of other experiments in which the role of these two subsets has been investigated. Further, despite an apparent decrease in CD8⁺ cells in class I^{-/-} mice, CD8⁺ cytotoxic T lymphocytes (CTLs) can be generated in large numbers following transplantation and may therefore be involved in the rejection process.

Cells involved in activation of the immune response

Mature splenic dendritic cells which express both class I and II MHC antigens are able to induce very strong primary immune responses to alloantigen. It is thought that the passenger leukocytes present within most or all tissues are members of the dendritic cell lineage. There is good evidence that such cells are able to migrate from a transplanted organ to the central lymphoid tissue, acquiring full T cell stimulatory activity where they can activate the immune system (direct antigen presentation). Depletion of passenger leukocytes from transplants has been shown under some circumstances to increase the survival of organ grafts in both experimental and clinical transplantation. The role of endothelial cells in provoking immunity to a graft is a subject of much discussion. Endothelial cells do not fall into the category of professional antigen-presenting cells, yet they do constitutively express MHC class II proteins (at least in humans) and therefore have at least part of the machinery required for CD4⁺ T cell activation. It is possible that their most important role in transplantation responses is to augment immunity and stimulate T cells which have already been exposed to antigen and thus are classified as memory or activated T cells.

Privileged sites

Allografts placed in certain 'privileged' sites may survive for prolonged times or even indefinitely. Probably the best known privileged site is the cheek pouch of the Syrian hamster, in which an allograft will survive indefinitely in an unsensitized animal. Other sites in which allografts or xenografts show prolonged survival are the anterior chamber of the eye, the cornea in humans, the testis and the brain. However, grafts placed at these sites will be rejected eventually in unsensitized recipients, or rapidly if the recipient is sensitized to the graft antigens. All of these sites have in common abnormal or reduced lymphatic drainage and it is possible that a delay in sensitization of the recipient affects the tempo of rejection. Recent experiments have shown that at least some of these privileged sites also express Fas ligand at very high levels. The suggestion from these data is that this Fas ligand induces apoptosis in Fas-expressing T cells, thus limiting their action in graft rejection. Indeed, insertion of cells expressing high levels of Fas ligand into a pool of syngeneic islet cells can protect the islets from rejection by an allogeneic recipient.

Efferent phase

T cell help and graft rejection

Because congenitally athymic (nude) and adult thymectomized, irradiated and bone marrow-restored (ATXBM) animals do not reject incompatible grafts, it is clear that T cells are required for graft rejection. It is also clear from adoptive transfer experiments that helper cells are essential for the initiation of the immune response to a graft. Thus, in most experimental models of transplantation, CD4⁺ but not CD8⁺ T cells are able to reconstitute ATXBM or nude animals with the ability to reject an allograft. This is slightly confused by the finding that only CD8⁺ cells are required to initiate graft rejection between certain mouse strains that differ in only a few amino acids of their class I molecules. The ability of CD8⁺ cells to cause rejection in this situation, however, seems to be a reflection of the high number of CD8⁺ helper cells activated in this strain combination, rather than a lack of requirement for T cell help. Although the adoptive transfer studies described above have shown that, perhaps not surprisingly, T cell help is required to initiate graft rejection, they give little indication of how graft rejection is effected, since both nude and ATXBM animals contain many leukocytes including B cells, macrophages, natural killer cells, and at least some cytotoxic T cell precursors. Any or all of these cells

may be recruited by T helper cells to cause tissue destruction.

Specificity of the effector phase

One key point about the effector phase of graft rejection is the exquisite specificity with which grafts can be rejected, a finding so elegantly demonstrated by Mintz and Silvers in a skin allograft model. In these experiments, allophenic or tetraparental mice derived from mice of different coat colors were used as skin donors. Skin was grafted to mice of either parental strain and the cells of nonidentical origin were rejected, leaving only the cells of recipient type intact and capable of hair growth. It is difficult to imagine that any mechanism of rejection involving nonspecific lysis of bystander cells (such as that involved in delayed-type hypersensitivity lesions) could be responsible for such specific tissue damage.

More recently, similar experiments have been performed by Rosenberg and colleagues. Interestingly they found that nonspecific inflammatory reactions could lead to total loss of grafts from allophenic animals if the area affected by the specific response was great enough. In other words, if the skin was predominantly of an MHC type different to that of the recipient, the entire graft could be lost. This suggests nonspecific inflammatory reactions may lead to tissue destruction if triggered by a massive and specific T cell response.

Antibody in graft rejection

Preformed antibodies reactive with MHC antigens are undoubtedly the cause of hyperacute rejection where grafts are destroyed within minutes of revascularization following binding of antibodies to the organ and complement fixation. The presence of such antibodies in potential donor-recipient pairs is now assessed before clinical transplants are performed using the cross-match test, and hyperacute rejection mediated by antibody is therefore avoided. Natural antibodies are responsible for the hyperacute rejection seen in discordant xenogeneic transplantation, although their target antigens are not completely defined. The role of antibody in acute and chronic rejection is less clearly understood and indeed there is usually a poor correlation of the presence of antibody with these types of rejection. However, work analyzing renal graft rejection across an MHC class I antigen disparity supports the concept that antibody may be involved in acute rejection.

Cytotoxic T cells

In tissue culture, cells from MHC mismatched individuals proliferate strongly in response to one

another in the mixed lymphocyte reaction (MLR). During this proliferation, cytotoxic effector cells (CTLs) are generated that are able to specifically lyse target cells carrying the same alloantigens to which they have been activated. The target cells are usually lymphocyte blasts or tumor cells that carry the correct MHC antigens. The majority of CTLs are CD8⁺ class I directed, but CD4⁺ class II directed CTLs may also be generated. In 1970, Hayry and Defendi suggested that the MLR was the complete *in vitro* correlate of graft rejection, the proliferation representing the afferent phase of the immune response to an allograft. This was a very attractive view and one which was widely held for many years. Indeed, CTLs may be recovered from grafts that are undergoing rejection. Further, cloned populations of CTLs have been shown to cause both tumor rejection and tissue destruction. However, more recently, several groups have recovered CTLs from grafts that will not be rejected and, further, grafts may be rejected in the apparent absence of CTLs. One problem with all these analyses is our questionable ability to assess the cytotoxic potential of cells using *in vitro* assays – it may be naive to assume that such assays accurately reflect the potential of cells to cause tissue damage or graft rejection *in vivo*. Indeed, Steinmuller and his colleagues have described CTL clones that have lost their ability to lyse ⁵¹Cr-labeled targets *in vitro* yet maintain their ability to cause tissue damage *in vivo*, and vice versa.

Some other evidence in favor of the involvement of CTLs in graft rejection comes from the work of several groups in which the tempo of graft rejection may only be completely restored to normal in T cell-deprived animals if both CD4⁺ and CD8⁺ cells are given at the time of transplantation. Other experiments implicating CTLs include those in which graft rejection is manipulated by injection of antibodies that react with CD4⁺ and CD8⁺ T cell subsets. In such experiments, greater prolongation of graft survival is often seen when both CD4⁺ and CD8⁺ subsets are depleted than when CD4⁺ cells alone are depleted. In summary, it seems likely that CTLs are capable of causing the tissue destruction associated with graft rejection but are unlikely to be the only cells involved and their presence within a graft may not always result in rejection.

Delayed-type hypersensitivity (DTH) and graft rejection

DTH reactions are specifically initiated via a CD4⁺, antigen-reactive cell. The DTH lesion itself is, however, nonspecifically effected and characterized by an infiltrate of lymphocytes and cells of the monocyte-macrophage lineage. It is noteworthy that the sever-

ity of DTH lesions varies greatly among different species, all of which reject allografts with comparable facility. Skin graft rejection across male-specific minor histocompatibility (H-Y) differences in mice correlates better with DTH responses than with CTL responses. Now that the nature of the H-Y antigen(s) is becoming clear it should be possible to assess more accurately the role of CTL and DTH reactions to H-Y in graft rejection. Activated macrophages are certainly found within rejecting grafts but this may simply be as a consequence of the tissue destruction that occurs in graft rejection. Indeed, large numbers of class II-positive macrophages may be seen in syngeneic skin grafts, presumably as a consequence of tissue damage rather than of an immune response.

Natural killer (NK) cells

NK cells do not require any activation in order to lyse a variety of tumor cell targets. It is unlikely that these cells are involved in the rejection of solid organ allografts for a number of reasons. First, they are found in high levels in nude animals which are unable to reject grafts. Second, they are present in grafts which are not rejected by, for instance, cyclosporine-treated or blood-transfused animals. Third, antibody treatments designed to deplete NK cells have no effect on graft survival.

Lymphokine-activated killer (LAK) cells

Lymphocytes cultured in high levels of interleukin 2 (IL-2) develop cytotoxic activity of an essentially nonspecific nature. Whether these cells are actually generated in *in vivo* immune responses remains to be clarified. Their role in solid organ graft rejection has not been studied, although they appear to be capable of causing tumor regression in both experimental and clinical settings.

The target cells of graft rejection

The precise target(s) cells of allograft rejection are not clearly defined, but it seems likely that damage to the vascular endothelium, which may express both class I and class II antigens, would result in rapid graft loss. The vascular changes that occur during graft rejection indeed suggest that this is the case. The parenchymal cells of the graft may also be targets for rejection, although it is likely that this will be secondary to the initial attack on the endothelium.

Cytokines and graft rejection

Cytokines clearly play an essential role in the regulation of all immune responses. The expression of cytokines in transplanted tissue has been studied

extensively, both in experimental models of transplantation and in the clinical setting. In allografts a predominance of the T_H1 -type cytokines (such as interferon γ) usually indicates the onset of rejection, although there are certainly exceptions to this rule. It has been suggested that, by contrast, a T_H2 -dominated response may be beneficial and indeed responsible for tolerance. While it is often the case that prolonged graft survival is associated with a maintained or even increased expression of T_H2 cytokines, there are very few examples in which tolerance can be explained on the basis of a T_H2 response. Indeed, it is possible to induce tolerance in animals that, through genetic manipulation lack IL-4. It seems probable that a T_H2 response may be less damaging to a graft than a T_H1 response and thus may provide a window in which the immune system can become tolerant of the graft.

Chronic rejection

Chronic graft rejection has now become the major reason for graft loss, yet remains poorly understood. It is suggested that both immunological (cellular and humoral) and nonimmunological mechanisms are involved in the damage that leads to eventual graft loss, but the immune effector mechanisms are ill defined. Experimental models of chronic rejection have begun to allow a description of the etiology of the obliterative arterial changes that are the hallmark of chronic rejection and may allow the development of therapeutic strategies aimed at preventing this problem.

Conclusions

The immune response that results in graft rejection is a complex phenomenon, with respect both to the manner in which the graft antigens are presented to, and recognized by, the host leukocytes, and in the effector phase of the response that generally results in graft damage. The CTL is still considered of primary importance in mediating tissue damage in graft rejection, but the DTH reaction may also be involved and is probably responsible for some of the later damage to a graft. Antibody is clearly involved in graft rejection in some special situations, but its role in acute and chronic rejection remains unclear. Specific regulation of these immune responses with resulting graft tolerance in the adult remains the goal of transplant biologists and, although achieved in many experimental models of transplantation, remains elusive in clinical transplantation.

GRAFT-VERSUS-HOST REACTION

Robertson Parkman, Division of Research Immunology and Bone Marrow Transplantation, Childrens Hospital of Los Angeles; University of Southern California School of Medicine, Los Angeles, CA, USA

The graft-versus-host reaction was first described by Billingham, Medawar and their colleagues. In their original publications the prerequisites for the graft-versus-host reaction were the infusion of immunocompetent cells into a recipient incapable of rejecting the cells and the existence of a histocompatibility difference between donor and recipient. Thus, the graft-versus-host reaction could occur following the infusion of homozygous cells into heterozygote recipients, but not in the reverse setting. The graft-versus-host reaction occurred in totally allogeneic hosts only if the recipient was immunosuppressed prior to the infusion of immunocompetent cells and was not observed in the recipients of syngeneic cells.

Graft-versus-host disease

Confusion exists as to the difference between the graft-versus-host reaction and graft-versus-host disease. Graft-versus-host reaction identifies only the immunologic events that occur as a consequence of the infusion of allogeneic immunocompetent cells into a susceptible recipient. It has become apparent, especially from the studies in germ-free animals, that the clinical manifestations of the graft-versus-host reaction (graft-versus-host disease) is dependent upon many environmental factors, including the presence of endotoxin, the age of the donor and recipient, the sex of the donor, etc. Thus, strain combinations exist in which no graft-versus-host disease occurs when transplants are done between germ-free animals. However, the introduction of bacteria into

the stable post-transplant chimera results in the development of clinical graft-versus-host disease, presumably secondary to the effects of endotoxin and other bacterial products/antigens. An extensive literature exists documenting the role of endotoxin in increasing the severity of graft-versus-host disease. Graft-versus-host disease is more frequently seen in the recipients of female, as opposed to male, immunocompetent cells.

Clinically, graft-versus-host disease can appear as one of two distinct forms. Acute graft-versus-host disease has its onset early following the infusion of donor immunocompetent cells and is characterized by the cytolytic destruction of the recipient epidermal cells, hepatocytes and gastrointestinal cells, producing a characteristic cutaneous erythroderma, elevation in hepatocellular enzymes and diarrhea. A high rate of fatality is found in both animals and humans with severe acute graft-versus-host disease due to the denudation of the gastrointestinal tract, epidermal sloughing, sepsis and bleeding. Individuals, who do not die from acute graft-versus-host disease, are at risk of developing chronic graft-versus-host disease, which has many similarities to autoimmune diseases, including sclerodermatous skin changes, the production of autoantibodies, etc. In model animal systems, graft-versus-host disease is usually produced by the infusion of homozygous donor immunocompetent cells into F₁ recipients or of allogeneic bone marrow cells into irradiated recipients. Graft-versus-host disease can be seen following the infusion of

peripheral lymphoid cells, splenocytes and bone marrow or the transplantation of lymphoid-containing organs, such as the small intestine.

Histocompatibility differences

Graft-versus-host disease due to antigenic differences at the major histocompatibility complex (MHC) can be due to either CD8⁺ or CD4⁺ T lymphocytes. Acute graft-versus-host disease caused by class I histocompatibility differences is due primarily to CD8⁺ T lymphocytes, many of which are cytotoxic T lymphocytes, whereas acute graft-versus-host disease due to class II histocompatibility differences is due to CD4⁺ T lymphocytes, some of which may be cytotoxic T lymphocytes, while others are helper T lymphocytes. The specificity of each of these effector cell types can be seen in strain combinations in which isolated class I or class II histocompatibility differences exist. A role for cytokines, in addition to cytotoxic T lymphocytes, has been demonstrated in acute graft-versus-host disease. The administration of antibodies to murine tumor necrosis factor α (TNF α) resulted in a reduction in mortality and the abolition of the histopathologic changes associated with acute graft-versus-host disease. These results indicate that cytokines, in addition to cytotoxic T lymphocytes, may be important effector mechanisms in acute graft-versus-host disease.

Graft-versus-host disease due to non-MHC antigenic differences is more complicated, and debate still exists as to its effector mechanisms. Most investigators, however, agree that both CD4⁺ and CD8⁺ T lymphocytes are involved in the pathogenesis of acute graft-versus-host disease due to non-MHC differences, although the relative importance of the CD4⁺ and CD8⁺ T lymphocytes is strain dependent. The CD8⁺ T lymphocytes have specificity for recipient restricted minor histocompatibility antigens, while the CD4⁺ T lymphocytes have specificity for the shared class II antigens. Based upon *in vitro* depletion experiments, the CD4⁺ T lymphocytes may produce the cytokines (interleukin 2 (IL-2), IL-4) required for the *in vivo* differentiation and growth of the recipient-specific CD8⁺ T lymphocytes. When animals with chronic graft-versus-host disease have been analyzed, primarily CD4⁺ autoreactive T lymphocytes without cytotoxic capacity have been identified. Chronic graft-versus-host disease is characterized histopathologically by increased collagen deposition. The autoreactive CD4⁺ T lymphocytes are capable of producing cytokines (interferon γ , TNF α , IL-4) which can stimulate fibroblast collagen production, suggesting that chronic graft-versus-host disease is primarily a cytokine-mediated disease. IL-

4 could also be responsible for the observed increase in autoantibody production. Animal experiments, therefore, indicate that histocompatible acute and chronic graft-versus-host disease, besides differing in their clinical presentation, also differ in their cellular effector mechanisms and suggest that the pathogenesis of acute and chronic graft-versus-host disease differ.

Human graft-versus-host disease

Graft-versus-host disease has its major clinical significance in human bone marrow transplantation. Graft-versus-host disease is also seen following the infusion of nonirradiated allogeneic blood products into immunosuppressed recipients, including patients with primary cellular immunodeficiencies and cancer. Graft-versus-host disease due to infusion of histoincompatible immunocompetent cells usually results in the death of the recipient. Graft-versus-host disease that is usually seen following histocompatible bone marrow transplantation is much milder and usually does not result in the death of the patient if prophylactic anti-graft-versus-host disease drugs are given. When human bone marrow is transplanted, it usually contains 20–40% peripheral blood mononuclear cells, meaning that as many as 5–10% of the total transplanted cells are mature peripheral blood T lymphocytes. Following the transplantation of histocompatible human bone marrow, acute graft-versus-host disease is a frequent occurrence. The prophylactic administration of methotrexate has reduced the incidence of significant graft-versus-host disease ($\geq$ grade 2) to 40%. Combined immunosuppression with cyclosporine plus methotrexate or cyclosporine plus steroids has further reduced the overall incidence of significant acute graft-versus-host disease to 20%. The presence of significant acute graft-versus-host disease ($\geq$ grade 2) is the major prognostic factor that determines whether chronic graft-versus-host disease will occur. Acute graft-versus-host disease usually develops 10–30 days after bone marrow transplantation and is characterized by a measles-like rash, elevation of hepatocellular enzymes and diarrhea. Elevation of serum IgE levels can also be seen. Factors that are predictive of an increased incidence or severity of acute graft-versus-host disease include transplantation from alloimmunized female donors into male recipients, increased donor/recipient age, and the lack of prophylactic anti-graft-versus-host disease therapy. Patients with acute graft-versus-host disease, who do not respond to prophylactic graft-versus-host disease therapy, are treated with steroids and/or antithymocyte globulin (ATG).

Transplantation between family members that differ at only a single HLA allele has demonstrated that class II histocompatibility differences produce more graft-versus-host disease than class I differences. The recipients of matched unrelated donor bone marrow have an increased severity and frequency of acute graft-versus-host disease than the recipients of histocompatible sibling bone marrow. Again class II histocompatibility differences produce more severe graft-versus-host disease than class I differences. Transplantation with unrelated cord blood results in less graft-versus-host disease, presumably due to the relative immunologic immaturity of cord blood T lymphocytes. If the transplantation of unrelated cord blood results in less acute graft-versus-host disease, greater degrees of histoincompatibility between donors and recipients may be possible.

Chronic graft-versus-host disease has its usual onset between 90 and 150 days after transplantation. Patients are characterized by increased collagen deposition with sclerodermatous skin changes, pulmonary fibrosis, gastrointestinal malabsorption and sicca syndrome. Patients are also characterized by an immunodeficiency to environmental antigens in the context of autoantibody production. Patients have a particular inability to make antibodies to carbohydrate antigens, predisposing them to an increased incidence of infections with respiratory bacteria. Patients with chronic graft-versus-host disease are aggressively treated with cyclosporine and steroids. Combination therapy has resulted in significant clinical improvement and increased patient survival. Because of their immunosuppressed status, patients with chronic graft-versus-host disease are placed on prophylactic antibiotics (trimethoprim and sulfamethoxazole) and monthly replacement intravenous immunoglobulin therapy.

Autologous graft-versus-host disease

A special form of graft-versus-host disease, which was first observed in rodents and has now been seen clinically, is autologous graft-versus-host disease. Autologous graft-versus-host disease is found in recipients undergoing autologous or syngeneic bone marrow reconstitution and receiving cyclosporine in the post-transplant period. They develop an acute form of chronic graft-versus-host disease, in which autocytotoxic T lymphocytes with a broad specificity for autologous class II histocompatibility antigens can be identified. Such autologous graft-versus-host disease appears to be due to the effects of cyclosporine and irradiation on thymic differentiation. Although the mechanism of autologous graft-versus-host disease is not certain, the increased frequency of

autoreactive T lymphocytes seen in autologous graft-versus-host disease animals suggests that thymic damage, leading to the decreased negative selection of autoreactive T lymphocytes during normal T lymphocyte ontogeny, may be the basis for the autologous graft-versus-host disease.

A graft-versus-leukemia effect has been seen in the recipients of allogeneic bone marrow transplants with acute graft-versus-host disease. The graft-versus-leukemia effect is seen in patients with chronic and acute myelogenous leukemia and to a lesser degree in acute lymphoblastic leukemia. Clinical experiments are now underway to determine if the effector mechanisms involved in acute graft-versus-host disease can be separated from the graft-versus-leukemia effect.

Graft-versus-host disease is the clinical manifestation of the graft-versus-host reaction. Acute and chronic graft-versus-host disease are still major problems found in human bone marrow transplantation. Many basic immunologic questions still need to be resolved before a total understanding of both the graft-versus-host reaction and graft-versus-host disease is achieved.

GRANULOCYTE COLONY-STIMULATING FACTOR (G-CSF)

T Michael Dexter, Department of Experimental Haematology, Paterson Institute, Christie Hospital NHS Trust, Manchester, UK

The colony-stimulating factors (CSFs) were characterized by their ability to facilitate survival and to promote clonal proliferation and development of hematopoietic progenitor cells *in vitro*. Granulocyte CSF (G-CSF) is one member of this family of glycoproteins, which also includes granulocyte-macrophage CSF (GM-CSF), macrophage CSF (M-CSF), and multi-CSF (also known as interleukin 3, IL-3). G-CSF was distinguished from the other CSFs by its ability to induce differentiation and clonal extinction in certain myeloid leukemia cell lines, and by its capacity to promote almost exclusively the development of neutrophils from normal hematopoietic progenitor cells. It shows a high degree of cross-specific activity, indicating strong evolutionary conservation.

Sources

Most tissues and freshly isolated monocytes, macrophages, fibroblasts and endothelial cells can produce G-CSF when cultured *in vitro*. Production *in vivo* is regulated, at least in part, by bacterial products: serum G-CSF levels are rapidly elevated in a variety of pathological conditions such as infection or following injection with bacterial endotoxin. Since this can occur in the absence of T lymphocytes or other leukocyte populations, cells of the nonhematopoietic tissues are presumably responsible for the production of the cytokine in response to the endotoxin. Indeed, *in vitro* data show that bacterial products can directly influence endothelial cells or fibroblasts to increase the production of G-CSF.

Molecular biology

Molecular cloning of human G-CSF has yielded purified material (rhG-CSF) that is biologically active in colony assays when used at a concentration of 5–10 pM. The mRNA encodes a 30 amino acid hydrophobic leader sequence that is characteristic of secreted proteins. A typical signal sequence cleavage site is followed by 174 amino acids, giving an *M_r* of 18 627: two disulfide bonds stabilize the molecule. Although native G-CSF is glycosylated, the sugar residues do not appear to be important for biological activity; recombinant material produced by *Escherichia coli* is apparently as active *in vitro* and *in vivo* as the native glycosylated material.

X-ray crystallography has shown that nonglycosylated G-CSF has four antiparallel bundles with crossing angles of 18°, a short 3–10 helix immediately after the first disulfide bond, and two long loops and one short loop connecting the helical core bundle. Although there is a structural relationship between G-CSF and other cytokines such as IL-2, IL-3, IL-6, erythropoietin and GM-CSF, it is most closely related to human growth hormone in terms of the four helices and folding and positioning of the helices within the core structure.

The gene for human G-CSF is single copy, does not share homology with other CSFs, and has been localized to the q21–22 region of chromosome 17 (unlike M-CSF, GM-CSF, IL-3, IL-4 and IL-5, which are found as a linked gene cluster on chromosome 5). This region of chromosome 17 is involved in the translocation between chromosomes 15 and 17 that is associated with acute promyelocytic leukemia.

Receptor

Single, high-affinity receptors, specific to G-CSF, are expressed on precursor and mature cells from the neutrophil lineage and some monocytes/macrophages. The receptor density varies from 30 to 3000 per cell and the K_d is about 100 pM. It is a 130–150 kDa glycoprotein, encoded by a single gene on chromosome 1 p35–p34.3, with a single transmembrane domain of 812 amino acids and an extracellular portion containing an immunoglobulin (Ig)-like domain, three fibronectin type-3 repeat units and the WSXWS motif common to the cytokine-receptor family. Ligand–receptor interaction is followed by rapid internalization of the complex and a slow degradation of the internalized G-CSF. Relatively little is known of the subsequent signal transduction events consequent upon G-CSF bonding to its receptor.

Hematopoietic target cells

G-CSF is a relatively poor stimulus for progenitor cell development – only a few colonies are found (in comparison with IL-3, GM-CSF or M-CSF) and these consist predominantly of mature neutrophils, although occasional monocytes and macrophages can be found. Generally, the colonies are small and contain 50–150 cells (cf. GM-CSF or IL-3 where colonies containing 10^4 – 10^5 cells can routinely be observed). However, G-CSF can work also in synergy with other cytokines: a combination of GM-CSF plus G-CSF or of M-CSF plus G-CSF can recruit proliferation and development of more primitive ‘target’ cells than either factor used alone.

In addition to its mitogenic effects on progenitor cells, G-CSF can prolong the survival time of mature neutrophils, and mature cells exposed to G-CSF demonstrate enhanced antibody-dependent cellular cytotoxicity (ADCC), and enhanced response to the chemotactic peptide *N*-formyl-Met-Leu-Phe in terms of the generation of the superoxide anion. These responses are presumably related to the role of G-CSF in the activation and recruitment of neutrophils in response to infectious agents.

Radioiodinated G-CSF has been used to determine its receptor-binding properties. It binds to (some) blast cells, promyelocytes, myelocytes, metamyelocytes and mature neutrophils, with the numbers of receptors increasing from around 300 (on blast cells) up to 3000 on mature blood neutrophils. A small proportion of promonocytes and monocytes also have G-CSF receptors, but cells of other maturing hematopoietic lineages are uniformly negative. Thus, the receptor data are in broad agreement with the

biological effects elicited by this cytokine. Analysis of leukemic cell populations has shown that receptors are present on most myeloid, but absent from lymphoid, malignancies. The receptor for G-CSF present on murine cells has recently been molecularly cloned and has some structural features shared by receptors for other CSFs and human interleukins.

Other target cells

It has been reported that G-CSF and GM-CSF can directly influence the proliferation and migration of endothelial cells *in vitro*. However, the physiological significance of this is unknown and, so far, no effect of G-CSF on neovascularization or angiogenesis *in vivo* has been reported. Also, certain solid tumor cell lines have demonstrated increased proliferative activity when exposed to G-CSF, but the significance of this effect is unclear and no growth stimulatory effect upon solid tumor cells has been reported in patients with malignant disease following treatment with G-CSF.

Preclinical and clinical studies

Existing data suggest that, in humans, G-CSF is the primary factor mediating neutrophil response to infection and neutropenia: in gram-negative and fungal infections, elevated blood G-CSF levels are found. In ‘knockout’ mice, lacking endogenous G-CSF, chronic neutropenia and impaired neutrophil function are found, suggesting that G-CSF is essential for maintaining a normal quantitative balance of neutrophil production during steady-state hematopoiesis in addition to its role in emergency granulopoiesis during infections.

In all mammalian species examined, the administration of G-CSF at a dose of about $10 \mu\text{g kg}^{-1} \text{ day}^{-1}$ leads to a dramatic increase in the numbers of neutrophils in the peripheral blood. A modest increase in the number of circulating monocytes and lymphocytes has also been reported, but no effect is seen on the levels of circulating eosinophils, basophils or platelets. In mice, G-CSF leads to a redistribution of hematopoiesis from the bone marrow to the spleen, presumably due to release and migration of early stem cells from the bone marrow to the spleen. Indeed, following treatment with G-CSF, circulating stem cell levels can increase up to 400-fold compared with controls. Such data have encouraged the use of cells harvested from the blood of patients treated with G-CSF as a source of stem cells for transplantation. Although long-term treatment of mice with G-CSF can lead to anemia as a consequence of suppression of erythropoiesis, neither

anemia nor thrombocytopenia have been consistently observed in patients following long-term treatment with this cytokine.

Phase I trials in patients (dose escalation and efficacy studies) have reproduced the effects seen in animals in terms of enhancement of circulating neutrophil levels (up to 15 times normal levels), a modest increase in monocytes and a dramatic increase in the number of circulating hematopoietic progenitor cells. The bone marrow of treated patients shows increased cellularity and a marked shift in the myeloid:erythroid ratio. Cell kinetic studies have shown that the increase in neutrophils arises via increased amplification in the maturation compartment in the bone marrow and that newly produced mature neutrophils are released into the circulation within 1 day, compared with a normal emergence time of 5 days. This effect of G-CSF is unlike that seen with GM-CSF or IL-3, where a normal emergence time of 5–6 days is seen.

Subsequent phase II and III clinical trials have shown that G-CSF can accelerate recovery of circulating neutrophil levels when given after chemotherapy in patients with malignant disease or following bone marrow transplantation. The clear advantages of this are reduced morbidity (i.e. decrease in infective episodes), shorter hospitalization, and dose intensification of chemotherapy. In

addition, G-CSF has been shown to be effective in recruiting myeloid leukemia cells into cell cycle and thus rendering them sensitive to chemotherapeutic agents, and in alleviating the neutropenia in patients with myelodysplasia, congenital neutropenia, aplastic anemia and acquired immune deficiency syndrome (AIDS).

GRANULOCYTE-MACROPHAGE COLONY-STIMULATING FACTOR (GM-CSF)

Philip S Crosier and Kathryn E Crosier, Department of Molecular Medicine, School of Medicine, University of Auckland, Auckland, New Zealand

Granulocyte-macrophage colony stimulating factor (GM-CSF) stimulates the proliferation, differentiation and functional activation of hematopoietic cells. The effects of this cytokine observed *in vitro* have also been demonstrated *in vivo*, and GM-CSF now has an established role in clinical medicine.

Sources

Cellular sources of GM-CSF include T lymphocytes, macrophages, fibroblasts and endothelial cells. GM-CSF synthesis in these cells is induced by such stimuli as antigen, lectin, interleukin 1 (IL-1), lipopolysaccharide, tumor necrosis factor α and phorbol ester.

GM-CSF is undetectable in the circulation, suggesting that it is produced locally and becomes compartmentalized within the extracellular matrix.

Assays

GM-CSF is assayed biologically using clonal assays in which progenitor cells from bone marrow or peripheral blood are suspended in the presence of growth factor in a semisolid matrix. After 1–2 weeks of culture, the number of granulocyte, macrophage and mixed granulocyte-macrophage colonies that have developed are scored. GM-CSF can also be assayed using factor-dependent cell lines as target cells in

short-term assays which utilize the uptake of tritiated thymidine as a measurement of cell growth. Proliferation assays to quantitate GM-CSF have also utilized as targets primary leukemic cells isolated from patients with chronic myelogenous leukemia and leukemic cell lines. Enzyme-linked immunosorbent assays (ELISA) are also available to measure GM-CSF.

Structure

The structure of GM-CSF has been determined by both partial amino acid sequence analysis and by deduction from the nucleotide sequence of cDNA clones. Mature murine and human GM-CSFs contain 124 and 127 amino acids, respectively. In each species the mature protein is preceded by a 17 amino acid leader sequence. Although murine and human GM-CSF are 54% identical at the amino acid level, there is no cross-species biological activity. Both murine and human GM-CSF contain two potential N-linked glycosylation sites and two internal disulfide bridges. Native GM-CSF is glycosylated to approximately 23 kDa. Bacterial-derived, nonglycosylated GM-CSF has high biological activity, indicating that the attached carbohydrate is not absolutely required for the molecule to be functional. GM-CSF has been demonstrated by X-ray crystallography to combine a two-stranded antiparallel β sheet with an open bundle of four α helices. This structure is similar to that of other hematopoietic cytokines.

Molecular biology

The GM-CSF gene in both mouse and human is present as a single copy of approximately 2.5 kb that contains four exons and three introns. It has been mapped in mouse to chromosome 11 and in human to the long arm of chromosome 5 in the region 5q21-q32. In humans the IL-3 gene is located 9 kb upstream and a number of other growth factor and growth factor receptor genes also map to chromosome 5q. Interstitial deletions in this region are observed in the 5q-syndrome and in a number of therapy-related myelodysplastic syndromes and leukemias. A similar clustering of genes has been observed on mouse chromosome 11. Regulation of GM-CSF expression is both transcriptional and post-transcriptional (by alteration of mRNA stability). The human GM-CSF gene contains a proximal functional promoter region (−620 to +34) and a powerful enhancer located 3 kb upstream.

Biological effects *in vitro*

GM-CSF acts as a proliferation and differentiation factor for granulocyte, monocyte and eosinophil progenitors, and as an enhancer of the function of mature effector cells. In combination with erythropoietin, GM-CSF supports the development of erythroid burst-forming units (BFU-E) and, in combination with IL-2, promotes the growth of some T cell lines. It has also been shown to have activity on dendritic cells.

GM-CSF enhances the function of granulocytes and macrophages in immune responses. It prolongs the lifespan of neutrophils and eosinophils *in vitro* and increases their metabolic activity. Direct effects on neutrophils include degranulation, inhibition of migration, changes in receptor expression (e.g. formyl-Met-Leu-Phe receptors) and alterations in cell shape. GM-CSF also primes the neutrophil for enhanced responsiveness to a secondary stimulus by increasing leukotriene synthesis and superoxide production. The ability of neutrophils, eosinophils and macrophages to phagocytose and destroy a variety of microorganisms is enhanced by GM-CSF. This molecule is also important in increasing antibody-dependent cellular cytotoxicity towards tumor cells.

The biological effects of GM-CSF are mediated through binding to specific cell surface receptors. Receptor-binding studies identified low- and high-affinity binding sites for GM-CSF on hematopoietic cells, but also on some nonhematopoietic tumor cell lines. Because placental tissue exhibited GM-CSF binding sites, this was used as source of cDNA to clone a low-affinity receptor for GM-CSF. A second subunit was subsequently identified that, together with the first (α chain), reconstituted high-affinity binding. This β chain also participates in the high-affinity binding of IL-3 and IL-5, together with their respective α chains. Both chains of the GM-CSF receptor are members of the hematopoietic cytokine receptor family and contain characteristic structural features in the extracellular domain, including four positionally conserved cysteines and a WSXWS motif. The cytoplasmic domains contain no catalytic regions but the β chain has a membrane-proximal region with limited homology to some other receptors of the family (box 1 and box 2 motifs). It has been demonstrated that a subfamily of cytoplasmic tyrosine kinases termed the Janus kinases (JAKs) are involved in signaling by the hematopoietic cytokine receptor family. Following ligand-dependent receptor aggregation, JAKs associated with the membrane-proximal region of the receptor are cross-phosphorylated. This results in phosphorylation of the receptor itself, which provides docking sites for

SH2-containing signaling proteins including SHC and phosphatidylinositol-3' kinase. The signal transducer and activator of transcription (STAT) proteins are a substrate for JAK kinase activity and are important mediators of cytokine responses. GM-CSF signal transduction has been demonstrated to involve the JAK 1 and JAK 2 kinases and STAT 5.

Biological effects *in vivo*

Transgenic technology has provided additional information regarding the biology of GM-CSF. Overexpression of GM-CSF in transgenic mice led to the accumulation of macrophages in the eye, resulting in blindness, and infiltration of macrophages into striated muscle. This demonstrated that high concentrations of GM-CSF during development may have pathologic consequences and sounded some warnings for clinical trials.

Targeted disruption of the GM-CSF gene has resulted in homozygous mice with no demonstrable defect in steady-state hematopoiesis, but a progressive accumulation of surfactant lipids and proteins in the alveolar space. Extensive lymphoid hyperplasia was associated with lung airways and blood vessels. It would seem that GM-CSF is not essential for basal hematopoiesis but has an unexpected, critical role in pulmonary homeostasis. This role was underscored in studies where mice deficient in the GM-CSF-receptor β chain were generated and showed a similar pulmonary pathology.

The biosynthesis of recombinant GM-CSF protein has permitted a wide number of studies to be undertaken on the efficacy of GM-CSF as a therapeutic agent. As predicted from *in vitro* studies, GM-CSF has proved to be a potent stimulator of hematopoiesis when administered *in vivo*. Administration is generally well tolerated but may be associated with bone pain and influenza-like symptoms, including fever, flushing, malaise, myalgia, arthralgia, anorexia and headache. These effects are usually mild, are alleviated by antipyretics and resolve with continued administration. At higher doses, GM-CSF has been associated with a capillary leak syndrome.

GM-CSF has been used to support both standard and intensified doses of chemotherapy. The expense of hematopoietic cytokines has necessitated critical examination of cost-effectiveness, and routine clinical use has generally not been recommended simply to reduce the degree, incidence or duration of neutropenia. The therapeutic end-points of GM-CSF administration in the chemotherapy setting are improved quality of life and survival. Use at present is largely to maintain dose intensity where dose reduction is not a reasonable alternative, and to

support a regimen that has a proven beneficial impact on survival and a high (>40%) risk of febrile neutropenia.

GM-CSF has been used to manage cytopenias associated with human immunodeficiency virus (HIV) infection and is capable of increasing neutrophil counts at relatively low doses, even with the concomitant administration of zidovudine (AZT), interferon α or ganciclovir. Clinical studies have focused on the role of GM-CSF as a supportive agent in the management of secondary infection and following chemotherapy for acquired immune deficiency syndrome (AIDS)-related non-Hodgkin's lymphoma. Potential alternative uses in AIDS include augmentation of neutrophil and macrophage function and enhanced tumor cell killing. There is some concern regarding the effect of GM-CSF on HIV replication in monocyte/macrophages, although data regarding this are at present conflicting.

GM-CSF was the first hematopoietic growth factor approved for use after autologous bone marrow transplantation. In this setting, like granulocyte colony-stimulating factor (G-CSF), it has been shown to reduce the duration of neutropenia, decrease the incidence of serious infection and use of antibiotics, and shorten hospital stay. GM-CSF has been used, either alone or with chemotherapy, to mobilize peripheral blood progenitor cells (PBPCs) for collection by apheresis and subsequent transplantation. These mobilized PBPCs appear to result in more rapid hematologic recovery than nonmobilized PBPCs or bone marrow alone. In allogeneic bone marrow transplantation, GM-CSF has been used with apparent success in the management of graft failure.

Ongoing and future studies should not only more clearly define the role of GM-CSF alone in the management of a variety of clinical situations, but also examine how this cytokine might be used effectively in combination with other modulators of hematopoietic development.

GRANULOMA

John L Turk, Department of Pathology, The Royal College of Surgeons of England, London, UK

The germ granuloma was introduced by Virchow in 1865 to describe certain well-circumscribed swellings consisting of what he thought was granulation tissue, found in a number of chronic infectious diseases including tuberculosis, leprosy, syphilis and leishmaniasis. Later authors, including Cohnheim in 1877, distinguished large, swollen, epithelial-like cells. These they called epithelioid cells and differentiated them from the lymphoid elements in these lesions. In 1893, Metchnikoff formally recognized that these cells were related to the cells he had newly described as macrophages. The relation between granulomatous diseases and delayed-type hypersensitivity was recognized by Zinsser in 1925. Cells of the mononuclear phagocyte series are now considered to be the most important feature of granulomas. Although granuloma formation is generally a tissue response to particulate or fixed material in the tissues, they are not necessarily associated with infectious diseases or with delayed hypersensitivity. Hypersensitivity granulomas can be produced by the metals beryllium or zirconium and in sarcoidosis, a disease in which the role of an infectious agent has yet to be identified. Nonimmunological granulomas occur in silicosis and following the injection of metallic compounds such as aluminum hydroxide and kaolin. Nonimmunological granulomas can also occur in chronic infections where there is a specific failure of cell-mediated immunity, as in lepromatous

leprosy, systemic leishmaniasis (kala-azar) and the systemic mycoses. The granulomas of tuberculoid leprosy and localized forms of leishmaniasis are examples of hypersensitivity (immunological) granulomas and are associated with strong delayed hypersensitivity reactions, as are the granulomas produced by beryllium and zirconium (Table 1).

The predominant cell that features in nonimmunological granulomas is the typical phagocytosing macrophage. In lepromatous leprosy, this foamy cell, often referred to as the 'Virchow' cell, is packed full of globi of *Mycobacterium leprae*. In immunological granulomas, the cells of the mononuclear phagocyte system take on the appearance of epithelioid cells. These cells are poorly phagocytic and may have a rough endoplasmic reticulum and Golgi apparatus presenting a plasmacytoid appearance (type A); other epithelioid cells (type B) present a more vacuolar and lysosomal appearance. It is generally thought that epithelioid cells have a secretory function. However, no specific secretory agent has, as yet, been identified. As well as epithelioid cells, hypersensitivity granulomas contain giant cells; these are generally of the Langhans type with peripherally placed nuclei. Giant cells as a whole do not have a rough endoplasmic reticulum. Other cell types seen include lymphocytes and fibroblasts. Collagen synthesis leading to fibrosis is a particular feature of hypersensitivity granulomas. The relation between epithelioid cell

secretory function and fibroblast activation has yet to be fully defined. However, there is some evidence of increased prostaglandin and cytokine activity. Patients with immunological granulomatous diseases and silicosis are particularly associated with increased fibrosis in the area of the granulomas. Extreme examples of this are in sarcoidosis and berylliosis as well as tuberculosis. Silicosis is the only example of a nonimmunological granulomatous condition associated with epithelioid cell formation, fibroblast activation, increased collagen synthesis, and fibrosis generally in the lung.

There are two hypersensitive granulomatous states associated with a diagnostic skin test. The lepromin reaction is induced by the intradermal injection of killed *M. leprae*. The granuloma can be detected between 2 and 3 weeks as a nodular skin lesion which, on histological examination, shows all the features of an epithelioid cell granuloma. This reaction is positive in patients at the tuberculoid end of the leprosy spectrum, but negative at the lepromatous pole. In sarcoidosis the intradermal injection of an extract of spleen from a patient with sarcoidosis produces a Kveim reaction. This reaction is a nodular granuloma maximal between 4 and 6 weeks which, when examined histologically, shows all the features of an epithelioid cell granuloma.

Tissue destruction leading to caseation and cavitation is a particular feature of tuberculosis and is rarely, if at all, found in other immunological and nonimmunological granulomas. One of the agents that has been postulated as a cause of caseation is tumor necrosis factor α (TNF α), which is released from mononuclear phagocytes particularly by the action of endotoxin and can lead to vascular endothelial damage and fibrin deposition. It could be that there is increased release of TNF α by mononuclear phagocytes in patients with tuberculosis in the presence of certain components of *M. tuberculosis*, and this may account for the regular occurrence of caseation in this disease. Caseation may be a feature of the epithelioid cell granulomas or gummas of tertiary syphilis, and at the other end of the spectrum, absence of caseation is a diagnostic feature of sarcoidosis.

The association between epithelioid cell granuloma formation and delayed hypersensitivity in a number of diseases would explain the large number of T lymphocytes in the periphery of these lesions. Experimentally, it has been shown by transfer studies that granulomas in schistosomiasis are T lymphocyte mediated. They are also smaller in neonatally thymectomized animals. However, the presence of plasma cells and eosinophils in many granulomas of helminthic origin would indicate that B cells might

Table 1 Classification of granulomas

1. Immunological	
	Tuberculosis
	Tuberculoid leprosy

	Zirconium
	Beryllium
2. Nonimmunological	
	Nontoxic, e.g. plastic beads, carbon particles, nontoxic metals (e.g. Fe)
	Toxic, e.g. silica, talc, asbestos
	Activation of C3, e.g. carageenan, kaolin, aluminum hydroxide

play an important part in their formation. Immunoglobulin and complement also may accumulate around eggs, particularly in *Schistosoma japonicum* infection. In immunological granulomas of T cell origin, it has been found that CD8⁺ T cells are found more peripherally in the granuloma, while CD4⁺ T cells are found more centrally.

The term 'foreign body' granuloma is used to cover the localized response to a wide range of substances that enter the body from the exterior. Granulomatous reactions may occur around thorns or other sharp objects that penetrate the skin. Many of these reactions are immunological responses against foreign antigens, either as part of the object or on microorganisms carried in by the object. Thus, the lesions are frequently epithelioid cell granulomas with giant cells and there is also fibroblast proliferation. Frequently, these lesions resolve by fibrosis. The lesions produced by talc are similar. Although talc is not antigenic, the reaction is probably related to its silica content. Silicosis does not fit easily into the simple classification of immunological/epithelioid cell granulomas leading to fibrosis and nonimmunological/phagocytosing macrophage granulomas without fibrosis. Silicosis is a highly fibrinogenic condition. It has been suggested that phagocytosis of silica leads to lysosomal damage. However, this is not the whole story as nonfibrinogenic granuloma-producing agents may have the same effect. It has been shown that asbestos, a silica-containing product, activates complement through the alternate pathway.

Mycobacterial diseases: the immunological spectrum of granuloma formation

The spectrum of granuloma formation, from the

Table 2 Ridley–Jopling scale for leprosy

	<i>Tuberculoid</i> (TT)	<i>Borderline</i> <i>tuberculoid</i> (BT)	<i>Borderline</i> (BB)	<i>Borderline</i> <i>lepromatous</i> (BL)	<i>Lepromatous</i> (LL)
Organisms (<i>M. leprae</i>)	0	0 or +	0 or ++	+++	+++

Histology	Epithelioid cells	Epithelioid cells	Epithelioid cells	Phagocytosing macrophages	Phagocytosing macrophages

tuberculoid or high-resistance tuberculoid form to the low-resistance-phagocytic macrophage form, is known as the Ridley–Jopling scale (Table 2). Patients in the middle points of the spectrum can ‘upgrade’ and move to a higher immune position or ‘downgrade’ to a lower immune position, dependent upon the bacterial load in the tissues. However, polar tuberculoid and polar lepromatous patients usually remain in a fixed position. Patients on the TT or BT points on the scale are usually lepromin positive. The 14-day lepromin test is generally known as the Mitsuda reaction; a 48 h delayed hypersensitivity component is referred to as the Fernandez reaction. Spectra of granuloma formation based on immunological reactivity similar to that found in leprosy have been described in tuberculosis and leishmaniasis. High-resistance and low-resistance forms of granulomas may also be found in systemic mycoses such as histoplasmosis, coccidiomycosis and blastomycosis. The relation between the granuloma of the high-resistance form of disease, which is a hypersensitivity phenomenon, and resistance to infection has been a matter of controversy over many decades. Evidence for a dissociation between these two phenomena has been accumulating for some time.

GRANZYMES

Joseph A Trapani, The Austin Research Institute, Heidelberg, Australia

'Granzymes' (granule-associated enzymes) are a family of homologous serine proteases expressed specifically in the cytolytic granules of natural killer (NK) cells and cytotoxic T lymphocytes (CTLs). Individual granzymes appear to have distinct functions and while one, granzyme B (graB) is a key mediator of target cell death, others fulfil a variety of immunological functions to do with lymphocyte migration, amplification of cytokine networks, chemotaxis and may even directly reduce the infectivity of some viruses. Upon receptor-dependent conjugate formation between the effector lymphocyte and a target cell, exocytosis of the granule contents rapidly results in the delivery of a lethal signal to the target cell, resulting in apoptosis. Recent interest in granzymes has centered on the synergistic actions of graB and the pore-forming protein perforin (copackaged with granzymes in cytolytic granules) in the induction of a calcium-dependent apoptotic cell death pathway. The role of graB in apoptosis induction is dependent on its key ability to cleave substrates at specific aspartate residues, a property it shares with a family of cysteine proteases implicated in apoptosis in a range of diverse biological systems.

'Granule exocytosis' is one of two important contact-dependent lymphocytotoxic mechanisms, the other being granule- and calcium-independent and triggered by a classical receptor/ligand interaction involving the Fas ligand (FasL, CD95L) on the effector and Fas (CD95, Apo-1) on the target cell. Spontaneous (gld, lpr) and engineered (perforin or graB) gene knockout studies in mice have shown that granule- and Fas-mediated pathways are likely to have distinct functions *in vivo*. Defects in granule-mediated apoptosis result in a seriously deficient cellular immune response against some viruses (including reduced CTL, NK and delayed-type hypersensitivity (DTH) responses) and delays in rejection of some allogeneic tissue transplants, whereas inactivation or absence of Fas or its ligand cause persistence of autoreactive T cells in the peri-

phery, with consequent potentially fatal autoimmune sequelae such as nephritis. Despite this apparent dichotomy of function, it is likely that some Fas-sensitive target cells may be killed by the combined actions of both pathways.

Perforin and granzymes are the principal granule-bound CTL/NK effector molecules

The initial studies implicating protease activity in cytotoxicity were performed during the early 1980s, using generic serine protease inhibitors. Two groups headed by Pierre Henkart and Jurg Tschopp were later responsible for purifying cytolytic granules from mouse CTLs and demonstrating that they could reproduce the cytolytic activity of intact CTLs. The granules largely consisted of a battery of distinct but homologous granzymes and a potent 67 kDa membranolytic protein (perforin) which produced membrane pores structurally and functionally akin to those induced by the complement membrane attack complex. As many as eight different mouse granzymes have now been cloned, however only five (granzymes A, B, H, trypsin 2 and Met-ase) have been identified in humans. The granzymes have the 'charge relay triad' (histidine, aspartate, serine) and key active site serine residues of classical serine proteases like trypsin and can be purified on the basis of physicochemical properties such as charge and size, or by affinity purification with specific antibodies. The granzyme protein backbone is typically 26–28 kDa and is decorated to a variable extent with N-linked carbohydrate.

Each granzyme displays a particular proteolytic specificity, determined initially by cleavage of model synthetic tripeptide substrates (Table 1). GraA and trypsin 2 are trypsin-like and cleave adjacent to basic residues, GraB has a preference for acidic residues, Met-ase cleaves best at nonpolar nonaromatic amino acids (especially methionine and leucine) and the cleavage specificity of graH is yet to be defined.

Table 1 Molecules characterized from the cytotoxic granules of cytotoxic lymphocytes^a

<i>Molecule</i>	<i>Size (kDa)</i>	<i>Species^b</i>	<i>Function/specificity</i>
<i>Lytic molecules</i>			
Perforin	65–70	H,M,R	Ca ²⁺ -dependent pore-formation and synergy with granzyme B
<i>Granzymes</i>			
GraA	60 ^c	H,M	Multiple; tryptase protease
GraB	28–30	H,M,R	DNA fragmentation, Asp-ase protease
GraC	30	M	Unknown, protease
GraD,E,F	30	M	Unknown, tryptase proteases
GraG	30	M	Unknown, protease
GraH	30	H	Unknown, tryptase protease
Met-ase	30	H,M,R	Unknown, Met-ase protease
Tryptase-2	30	R	Unknown, tryptase protease
Leukophysin	30	H	Intracellular processing of cytotoxic granules
<i>Miscellaneous</i>			
Calreticulin	50	H,M	Chelates free Ca ²⁺ and keeps perforin inactive
Proteoglycans	>200	H,M,R	Bind activated granzymes electrostatically

^bH, human; M, mouse; R, rat.

^cDisulfide-linked homodimer of 30 kDa subunits.

Granzymes are synthesized as pre-propeptides. Following cleavage of classical leader peptides, they are transported through the Golgi, then targeted to the lysosome-like granules by binding to mannose-6-phosphate receptors. Immediately prior to packaging, cleavage of a remaining N-terminal dipeptide by dipeptidylpeptidase I results in refolding of the mature N-terminus into a cleft in the molecule, approximation of the 'charge-relay' residues and acquisition of protease activity. All granzymes are basic molecules (pI in the range 8–11) and are retained in cytolytic granules (pH ~5.5) electrostatically bound to chondroitin sulfate proteoglycans which are present in high concentration.

Perforin and graB synergize to cause apoptosis

In early studies, purified perforin was demonstrably a potent lysin (particularly for erythrocytes) but by itself was unable to reproduce apoptotic features such as blebbing of the cell membrane, DNA fragmentation and nuclear collapse in nucleated cells. Paradoxically, perforin-deficient mice first produced by Kagi and Hengartner exhibited normal T cell development and cytokine secretion but were immunodeficient due to a markedly reduced ability to induce target cell apoptosis. Kagi's observations were consistent with the hypothesis advanced by Greenberg and his colleagues that the combination of graB (fragmentin-2) and tiny (sublytic) doses of perforin could synergize to produce DNA fragmentation. Greenberg indeed demonstrated that cells

exposed to just these two purified molecules underwent apoptosis. Like perforin, graB applied alone to cells did not cause apoptosis. The requirement for an 'Asp-ase' specificity was demonstrated in that proteolytically inactive graB could not produce apoptosis, while other granzymes with non-Asp-ase activities (fragmentins 1 and 3, both of which possess trypsin-like activity) produced far slower apoptotic changes in combination with perforin.

Over the past several years, the mechanism of granzyme/perforin synergy has been the topic of intense investigation. Target cells loaded with protease inhibitors such as aprotinin could withstand apoptosis by CTLs, suggesting that graB acted intracellularly. This was confirmed by our own studies with purified fluorescein-conjugated graB which showed that cells co-exposed to perforin rapidly took up graB into the cytoplasm and ultimately also into the nucleus. These results were further supported by immunoelectron microscopy, which demonstrated graB within cytoplasmic vacuoles and free in the cytosol, while perforin staining was confined to the target cell membrane. Because it can form membrane pores, perforin had long been postulated to permit the diffusion of toxins such as granzymes into target cells. However this 'simple diffusion' model seems unlikely to be valid, as cells exposed to graB alone became vacuolated and contained cytoplasmic graB. Furthermore, graB/perforin-induced apoptosis could not be reproduced by substituting alternative pore-forming and membranolytic agents (including complement) for perforin. Overall, these findings suggested a highly specific requirement for graB

which cleaves intracellular substrates and the generation of an equally essential but yet undefined signal at the cell membrane by perforin.

As perforin and graB can kill a very broad variety of cells, it is likely that the signal generated by perforin utilizes a pathway present in virtually all cells. Whether the uptake of graB is receptor-mediated and/or due to endocytosis remains unclear. GraA has been shown to cleave the thrombin receptor and possibly other similar, unidentified cell surface receptors. Perforin, by contrast, undergoes a change in its tertiary structure from a globular to an extended configuration in the presence of calcium ions and binds to phosphorylcholine moieties in natural (and artificial) membranes to form oligomeric polyperforin clusters consisting of up to 18 monomers.

Generic cell death cysteine proteases are activated by graB cleavage

Studies in the helminth *Caenorhabditis elegans* have elucidated a key cysteine protease, CED-3 with Aspase specificity that is essential for the death of 131 somatic cells programed to undergo apoptosis during normal embryogenesis. The first mammalian homolog of CED-3 recognized was interleukin 1 β -converting enzyme (ICE), which was initially identified for its cleavage (at Asp residues) and activation of IL-1. All the caspases (ICE-like proteases) are synthesized as proenzymes which require cleavage at a specific Asp residue to produce an active heterodimeric molecule. Further autoprocessing then results in cleavage (also at Asp) of the propeptide, resulting in the fully active mature form. Expression of active ICE in a variety of cell lines resulted in apoptotic cell death. Subsequently, three subfamilies of related cell death proteases have been identified, whose individual members share closest structural similarity to either CED-3, ICE or ICH-1 (Nedd-2). It is the current view that some or all of these proteases are expressed in an inactive form in virtually every mammalian cell, and can be activated in response to a very diverse range of apoptotic stimuli including toxins, irradiation, growth factor withdrawal and intracellular pathogens.

That the Aspase activity of graB was indispensable for perforin/grab-mediated cell death strongly suggested it might activate ubiquitous cysteine protease cell death pathways. The lack of requirement for protein or RNA synthesis in CTL/NK-mediated apoptosis is consistent with latent cytoplasmic ligands/substrates 'ready' for cleavage by graB. Strong evidence now exists that graB can cleave multiple cell death proteases of the CPP32 (CED-3-like) subfamily that constitute a protease cascade in the

cytoplasm of target cells (Figure 1). CPP32 (also termed apopain and YAMA-1) activation by cleavage at Asp175 is followed by autoprocessing at Asp9, resulting in the fully active 19/12 kDa form that can cleave nuclear structures such as poly-(ADP ribose) polymerase (PARP). Cleavage (and inactivation) of PARP and other enzymes including DNA-dependent protein kinase (DNA-PK) has been identified in nuclei early in the apoptotic event. This can result in curtailed DNA repair and derepression of nucleases that then cleave exposed internucleosomal sites on DNA, contributing to DNA degradation and precipitating nuclear breakdown. In addition, graB can activate cytoplasmic proMch4 which in turn cleaves proCPP32 and proMch3, further amplifying the proteolytic cascade. Activation of Mch2 then results in the proteolysis of structural nuclear proteins such as lamins.

Evidence also exists that some graB substrates, such as proMch4 and proMch5 (FLICE), are high in the proteolytic cascade, and may also be able to couple Fas ligation to downstream proteolytic events. This is achieved in that proMch4 and proMch5 both contain two N-terminal FADD-like domains. These regions may associate with FADD bound to the cytoplasmic domain of Fas following FasL binding and receptor aggregation, and lead to activation of the cysteine protease domains of Mch4 and Mch5 to trigger downstream events in the cysteine protease cascade. Thus, in some instances CTLs may be able to activate proMch4/5 via Fas, and in other instances may use graB to activate them directly.

Remarkably, some viruses have developed ways of subverting generic cell death pathways by carrying protease inhibitors (serpins) whose expression can subvert 'altruistic' apoptosis of a cell, leading to a prolongation of the cell's life and greater time for viral replication and assembly. For example, the protein encoded by the cowpox crmA gene can block ICE activation and prevent apoptosis, while the baculovirus protein p35 can derail apoptotic mechanisms by a similar process. Serpins may also inhibit both cysteine and serine proteases of like-specificity (cross class inhibition). It is interesting that crmA is far more effective at blocking ICE than graB, suggesting that cells in which ICE activation has been blocked might still be susceptible to CTL/NK-mediated apoptosis due to graB.

Other functions of granzymes

Due to a multiplicity of protease specificities, granzymes have been suggested to contribute to many lymphocyte functions including extravasation

Figure 1 A hypothetical outline of the granule exocytosis mechanism of cellular cytotoxicity. Upon receptor-mediated conjugate formation between the effector lymphocyte and the target cell, cytolytic granules containing perforin and graB become oriented towards the site of cell–cell contact ('polarization'). Exocytosis of granule contents into the closed space between the two abutting cells permits perforin to intercalate the target cell membrane and polymerize in a Ca^{2+} -dependent manner. This generates a key signal permissive for apoptosis, the nature of which is poorly understood. Simultaneously, graB (and presumably other granzymes) enter the target cells, possibly by endocytosis, and are liberated into the cytosol. The Asp-ase activity of granzyme B is then instrumental in initiating a protease cascade within the target cell. Granzyme B cleaves (and activates) components of the apoptotic cascade at highly specific aspartate residues, resulting in activation of upstream proteases including Mch4 and Mch5 (FLICE), as well as CPP32 and ICE, which exert their effect further downstream. The result is amplification of the cascade and production of further activated proteases which can neutralize DNA repair enzymes such as PARP and DNA-PK and structural nuclear proteins such as lamins. This leads to DNA fragmentation and nuclear collapse, and the familiar apoptotic morphology. ProMch4 and ProMch5 (or highly analogous proteases) may also be recruited to the inner surface of the plasma membrane to subserve FasL-mediated signal transduction. These proteases contain conserved FADD-like domains which may interact with FADD molecules bound to the cytoplasmic tail of Fas upon Fas ligation. This interaction with FADD could result in activation of Mch4 and Mch5 with triggering of the proteolytic apoptotic cascade in the absence of granzyme B.

through capillary endothelium and penetration of intercellular connective tissue by mature T cells. GraB was also able to cleave molecular interactions between certain tumor cell lines and extracellular matrix proteins via the Arg-Gly-Asp (RGD)-binding motif, thereby inhibiting cell proliferation. To date, specific functions for Met-ase, graH and tryptase 2 have not been elucidated, however Met-ase is interesting in that its expression is restricted to NK cells, and therefore presumably plays a specific role in NK function.

The trypsin-like activity of graA has been shown

to cleave several connective tissue proteins including fibronectin and collagen *in vitro*. GraA can also cleave the thrombin receptor at the sequence Arg-Ser-Phe-Leu-Leu on various cells, stimulating such pleomorphic effects as contraction of processes on astrocytes and secretion of IL-6 and IL-8 from monocytes. GraA can also be trophic for fibroblasts and B lymphocytes, presumably by transducing a proliferative signal by cleaving analogous cell surface receptors.

Perhaps most remarkably, mice with a targeted disruption of the gene encoding graA generally dem-

onstrate normal immune-mediated apoptosis, but are extremely susceptible to infection with the poxvirus *Ectromelia*, possibly as the result of an inability to cleave envelope proteins that mediate adhesion to cell surface receptors. This is an important finding, as it indicates that some granzymes may have evolved highly specialized functions which are distinct from a direct role in cytolysis. The delineation of such specific granzyme functions will be a laborious task in a world populated by an almost limitless array of pathogens.

GRAVITY, EFFECT OF SPACE FLIGHT ON IMMUNITY

William R Beisel, Department of Molecular Microbiology and Immunology, The Johns Hopkins School of Hygiene and Public Health, Baltimore, Maryland, USA

Soon after astronauts, cosmonauts and experimental animals began to travel in outer space, postflight studies of their immunological markers revealed differences from preflight controls. Differences included neutrophilia, slight T cell lymphopenia and a diminished blastogenic responsiveness of T cells in postflight blood samples. Eosinophilia was sometimes seen, even after flights of only several days duration. Neutrophilia (observed also in animals) was almost

always present, reaching values 2–3 times above normal, but there were no accompanying increases in band forms or other immature cells.

Lymphopenia, most frequent and consistent in cosmonauts who participated in prolonged missions, was typified by reductions in numbers of T cells and natural killer (NK) cells. Rats exposed to the microgravity of outer space for 20 days showed postflight hypoplasia of spleens and thymic glands, with

a markedly reduced number of lymphocytes in these tissues.

Changes were also noted in the postflight concentrations of immunologically important plasma proteins, including immunoglobulins, complement components, lysozyme, interferon and α_2 -macroglobulin.

Although postflight laboratory abnormalities reverted to normal within a week or two, they were not the only immunological concerns. Minor infections occurred with some consistency during space flights. Careful postflight dental examinations often revealed areas of newly acquired gingival inflammation. Also, the microbiological environment of space vehicles showed consistent changes (in both the US and USSR programs), with decreases in anaerobic bacteria and fungal isolates, and increases in potentially pathogenic organisms.

Despite recirculation of cabin air through microfilters, microgravity caused a suspension of food particles and droplets of liquids from all sources, including waste disposal systems. Thus, microorganism-containing aerosols tended to be the rule, rather than the exception. It was not surprising then, that the microflora of space travelers also showed extensive alterations. A broad redistribution of microbial species occurred among crew members, with increased numbers of body sites harboring microorganisms. Altered body microflora of space travelers included an increased number and variety of dermal organisms, and the presence of potentially virulent bacteria (including *Mycoplasma* and *Staphylococcus*) on the upper respiratory mucosa.

Because of concerns about the immunological effects of prolonged exposure to microgravity, NASA program managers sought the advice of senior immunologists. Ensuing research recommendations, provided by a FASEB Committee in 1985, were widely implemented during the next decade in both the US and USSR space programs. Inflight studies were conducted in humans, experimental animals and cultured cells, and ground-based surrogate model systems were developed. Immunological data on space flights in excess of several weeks were almost exclusively Russian.

Granulocyte and monocyte-macrophage findings

Granulocytosis was observed consistently in astronauts after short duration shuttle flights, but numbers of eosinophils and monocytes tended to decline after 6–8 days in space. Similarly, increased numbers of blood neutrophils were also seen in postflight rats, while eosinophil and monocyte counts were reduced. No reports have mentioned any effects of micro-

gravity on granulocyte diapedesis, chemotaxis, phagocytosis or superoxide formation.

Marrow cells obtained from rats flown in space showed decreased responses to granulocyte-monocyte colony-stimulating cytokines. Rat monocyte-macrophages also showed a reduced spreading, *in vitro*, and their differentiation was inhibited. There was an increase in a population of smaller, less granular blood monocytes which failed to express receptors for insulin or insulin-like growth factor I.

Cell-mediated immunity and T cell changes

The more recent studies of lymphoid cells confirmed a modest depression in cell-mediated immunity after both short and long (over 1 month) space flights. Inducer and cytotoxic T cell populations declined. Decreased numbers of both CD4⁺ and CD8⁺ lymphocytes were found in postflight blood samples of 30 shuttle astronauts. Humans were also found to have postflight reductions in phytohemagglutinin-triggered blast transformation of cultured blood lymphocytes. After prolonged stays in space, the proliferative index of cosmonaut T cells showed reductions in xenogenic graft-versus-host reactions.

Human NK cells showed reduced numbers and cytotoxic activities after both long and short space flights. NK cells from the marrows and spleens of rats flown in space showed significantly inhibited *in vitro* cytotoxicity for target cells, although their binding to these cells appeared to be unaffected. The surface expression of some cytokine receptors was reduced in rat NK cells.

Delayed-type dermal hypersensitivity (DTH) reactions showed reductions, or even disappeared, during protracted stays in space. When tested during space missions, DTH reactions were consistently reduced after the fourth day of weightlessness. Inflight measurements of DTH were facilitated by the use of a multitest skin puncture device that simultaneously injected predetermined doses of seven recall antigens and one control.

Cell-mediated immunity was also studied in rats. After short flights, rats showed decreased numbers of blood CD4⁺ and CD8⁺ lymphocytes. The proliferative response of rat spleen cells to mitogens or to interleukin 2 (IL-2) was inhibited after 1–2 week flights. After 10 days in space, the phenotype of rat lymph node or spleen lymphocytes showed several tissue-specific differences, including an increased percentage and fluorescent intensity of splenocytes which expressed CD4⁺ and CD8⁺ markers, as well as the integrins LFA-1 α and β . In contrast, these

markers remained unchanged, or showed decreases, in lymph node cells from the same rats.

The response to concanavalin A of cultured cells from lymph nodes (but not spleens) of space-flown rats was depressed, and could not be restored by supplementation with either IL-1 or IL-2. However, these cultured cells showed normal responses to other mitogens, normal production of IL-2, and normal expression of surface markers. Because some of the immunological effects of microgravity appeared to be lymphoid organ specific, it was postulated that the findings may have been influenced by variations in lymphocyte trafficking, brought about by body fluid compartment shifts associated with microgravity.

Humoral immunity and B cell observations

In contrast to the expanding database showing subtle dysfunctions of cell-mediated immunity, evidence has not shown the presence of concomitant defects in humoral immunity. After space flight, B cell numbers have decreased in rats, but their percentages, relative to total lymphocyte counts, remained unchanged. In a single study, B cell responses to lipopolysaccharide were increased in rats flown in space for 19 days.

The few attempts to study the antibody-mediated humoral immune system have been inconclusive. However, the productive phase of the specific immune response to T cell-dependent antigens was not inhibited by space flight. *In vivo* responses to antigenic challenge have yet to be reported. During long space flights, immunoglobulin A (IgA) and IgM concentrations were sometimes increased, but IgG values remained constant.

Cytokine responses

The cytokine network is influenced by space flight, with changes being observed in preliminary, exploratory studies of the production and activity of interferons, interleukins, colony stimulating factors and tumor necrosis factor. After long flights, lymphocytic production of IL-2 and interferon was significantly decreased in both humans and rodents. In contrast, human lymphocyte cultures produced interferon more intensely during shorter spaceflights, but responded poorly to concanavalin A stimulation. In addition, the ability of cultured human postflight lymphocytes to express surface IL-2 receptors was blunted, but this expression could be restored by a protein kinase C-activating phorbol ester. Lymphocytes of rats flown on a 10 day space mission showed a decrease in IL-2 production in response to a T cell

receptor-independent mitogen, but not to receptor-dependent mitogens. Lymphocyte-produced interferon, but not IL-3 production, was reduced in rats after 6 days in space.

Cell culture studies in microgravity

Single cells in culture change their behavior when studied in the microgravity of space. When a standardized lymphocyte-monocyte population was isolated from blood, resuspended in culture fluid, and flown in space, monocytes virtually failed to produce IL-1, and the activation of lymphocytes by concanavalin A was markedly inhibited. However, when these same cells were attached to microcarrier beads before a flight, T cell activation was doubled, and their production of interferon and IL-2 was greatly enhanced. It thus appeared that certain immunological effects of microgravity were caused by altered cell-to-cell interactions.

Conclusions

Although a myriad of questions remain, available evidence clearly defines a blunting of cellular immune mechanisms during space flight. But not all immunological functions are affected equally. The major variable during space flight is microgravity, with its primary impact on the distribution of body fluids and on cell-to-cell adhesions and interactions, and their secondary immunological consequences. But microgravity is not the only variable that must be considered. Short- and long-term effects of ever-varying solar and space-generated radiation can have troublesome, but yet unquantified effects on the immune system of space travelers. The altered and redistributed microbiological flora of space vehicles, and their crews, undoubtedly impact on body defenses and immunological functions, as do stress-induced responses of the endocrine and neuroendocrine systems.

Infectious diseases do occur with some frequency during space flights, but the clinical relevance of documented immune system changes has not been proven. Although the immunological dysfunctions observed in laboratory tests have not as yet been accompanied by serious communicable infections among crew members, immunological concerns remain highly relevant whenever longer and more distant space travels are planned.

GUINEA PIG, INBRED STRAINS OF

Ethan M Shevach, Laboratory of Immunology, National Institutes of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland, USA

The most widely used inbred strains of guinea pig in immunologic studies are the strain 2 and strain 13 animals which have been maintained for many years at the National Institutes of Health in Bethesda, Maryland, USA. These two strains originated from a colony maintained by the Department of Agriculture in Washington, DC. In 1896, this colony was moved to Bethesda, a distance of 11 miles. However, during the course of the move, the covered wagons containing the guinea pigs encountered a severe rainstorm. Following an outbreak of pneumonia, only 54 animals from the original colony of 800–990 animals survived. In 1906, a series of experiments to study the effects of inbreeding were started and 24 inbred families were established. Family 2 and family 13 originated from distinct males. In the 1920s, a crisis in funding led to the elimination of most of the inbred families, but families 2 and 13 were preserved because they were the most vigorous. These two strains of animals were used by Sewall Wright in studies of the population genetics of special traits including spotting, digit number, otocephaly, sizes and shapes of internal organs, and resistance to tuberculosis.

MHC class II molecules

Although strains 2 and 13 animals were also used by Wright for studies of transplantation antigens, very little information is available about the results of these studies. It was shown that the two strains had become sufficiently homozygous for pieces of organs transplanted between members of the same strain to

be accepted. In the late 1950s, it was shown that intrastrain skin grafts were successful, with no indication of Y chromosome incompatibility, as shown by the acceptance of male skin by females. All the interstrain grafts were rejected, with a mean survival of 8 days. An estimate of the number of histocompatibility gene differences was derived by challenging 27 F2 individuals with grafts from each parental strain. Fourteen grafts survived, giving a survival rate of 26%. This level of survival would correspond to five independent genes. The distribution of survival ranged from 8 to 52 days, with a suggestion of two modes at 8 and 14 days. Thus, it seemed possible that two major histocompatibility complex (MHC) loci could separate the two strains.

The guinea pig was used as an experimental animal for a large number of immunologic studies in the 1960s and 1970s, including the identification and characterization of MHC-linked immune response genes. Because inbred strains 2 and 13 animals differed in the expression of these genes, cytotoxic antisera were raised by cross-immunization of the strains. Comparative studies of the tissue distribution and the biochemical properties of the antigens identified by anti-2 and anti-13 sera demonstrated that they appeared to recognize cell surface antigens which were the guinea pig homologs of the products of the I region of the mouse H2 complex. These antigens were restricted in their expression to lymphocytes and monocytes/macrophages and could not be identified on nonlymphoid cells. In contrast to other species, guinea pig Ia antigens were readily identifiable on resting T cells, although

their expression is less than that seen on B lymphocytes.

Biochemical studies of the antigens identified by anti-2 and anti-13 sera confirmed their relationship with the murine I region products. At least three different types of Ia-bearing molecules, each with a characteristic molecular structure, could be identified. Sequential precipitation studies have shown that the Ia2 determinant expressed by strain 2 and Ia3 and Ia5 determinants expressed by strain 13 animals can be found on molecules composed of 25 and 33 kDa chains in noncovalent association. The Ia4 and Ia5 determinants of strain 2 and Ia7 determinants of strain 13 are borne on 58 kDa molecules in which the two chains are linked by disulfide bonds. The Ia1 and Ia6 determinants of strain 13 are found on a single chain structure of 26 kDa. These findings are most consistent with a model that the guinea pig I region is composed of three subregions, each of which encodes an Ia determinant borne on a molecule with a characteristic chemical structure.

MHC class I molecules

The identification of guinea pig MHC class I molecules was facilitated by analysis of cytotoxic antisera independently raised by cross-immunization of random bred guinea pigs maintained in a closed colony by de Weck at the Institute for Clinical Immunology, Bern, Switzerland. Three sera were obtained which identified antigens controlled by a single locus or region. The antigens identified by these sera were termed GPLA antigens B1, B2, and B3 (originally B,C,D). Strain 2 and strain 13 animals were both found to bear the B1 antigen and to lack B2 and B3.

A number of strains were established by de Weck and coworkers which were homozygous for the B1, B2 and B3 antigens. An additional antigen termed S was identified as was found to be present in inbred strain 2, strain 13 and some outbred animals. Antigen S was distinct from the antigen identified by anti-B1 sera, although some anti-B1 sera prepared in B3 animals also contained anti-S activity. Almost all B2-bearing outbred animals were S positive, whereas B3-bearing outbred animals were uniformly S negative.

Studies of the tissue distribution of the B series of antigens demonstrated that, in contrast to the antigens identified by anti-2 and anti-13 sera, they were readily identifiable on all cells, including nonlymphoid cells. The identity of these antigens to murine and human MHC class I antigens was confirmed by immunoprecipitation studies which revealed that the B antigens were composed of two chains of molecular weights of approximately 12 and 45 kDa. The 12 kDa peptide was shown to be the guinea pig equivalent of human β_2 -microglobulin. The biochemical characteristics of the S antigen were identical to those of the B antigens and it is likely that S represents the product of a second MHC class I locus.

Distribution of MHC antigens in various inbred strains

Table 1 summarizes the distribution of all the known specificities of the guinea pig MHC (GPLA complex) in the different strains that have been studied. For reference, we have included the known genetic polymorphisms of properdin factor B and the second and fourth components of the classical complement pathway. The genes coding for these three complement

components are also linked to the GPLA complex. The order on the chromosome is arbitrary and the Ia antigens have been grouped on the basis of structural homology. In studies of outbred animals, there is a closer association between the B- and S-region antigens than between either the B- or S-region antigens and any of the I-region antigens. It is therefore likely that in the guinea pig, the I region lies outside the regions coding for the two MHC class I antigens. It has been observed in breeding studies that a cross-over occurred between the C4 allotype and the Ia antigens, which suggests that the region for complement proteins (Cp) maps either between the B and S regions and the I region or outside the rest of the GPLA complex.

Although the inbred guinea pig was widely used in the past as an experimental model for studies in immunology, very few studies have continued to use

inbred guinea pigs and large numbers of these animals are no longer available.

H

H2 CLASS I

Jeffrey A Frelinger and **Edward J Collins**, Department of Microbiology and Immunology, University of North Carolina, Chapel Hill, North Carolina, USA

Mouse class I major histocompatibility complex (MHC) encompasses the classical class I genes (also known as class Ia genes) K, D and L as well as approximately 25 additional sequences (known as class Ib, formerly known as nonclassical class I) which include the TL and Qa region genes and the less closely related CD1 genes. Class Ia molecules survey the proteins produced inside cells and display a selection of peptides derived from those proteins on the cell surface for inspection by T cells. This allows the immune system to constantly monitor the array of proteins produced by cells and detect those which are infected by viruses or bacteria by the appearance of new peptides bound to class I proteins. This same function can also be of use in detecting tumors; especially those caused by viruses. The function of the class Ib proteins is largely

unknown, but some have been shown to bind antigens and present them to T cells.

History

Mouse MHC class I proteins are encoded by a multi-gene family of about 30 members. The classical antigens K, D and L, were first described by Peter Gorer who was attempting to define blood groups in mice in a manner similar to Rh blood groups in humans. Gorer found that if he immunized mice of one inbred strain with cells from another he could produce antibodies that would agglutinate the red blood cells of the donor and some other strains, but not the recipient strain. The agglutinating activity which would become H-2 was first defined as antigen II. The most

important breakthrough came when he collaborated with George Snell and showed that the genetic locus responsible for the blood groups he studied, was the same as the locus Snell studied which defined tumor graft rejection. Coupled with Snell's first production of congenic mice, this allowed the genetic definition of the complex H-2 locus. This complex is now referred to as H2. The congenic strains allowed Snell and many other investigators to define the function of the MHC by comparing the immune responses of strains that differed only in the H2 complex.

Structure of class I proteins

The K/D/L proteins are trimers consisting of β_2 -microglobulin, which is invariant, a polymorphic heavy chain and a highly variable peptide. The 45 kDa polymorphic K/D/L heavy chain is further divided into specific domains. The $\alpha 1$ and $\alpha 2$ domains each donate a helix and four strands of anti-parallel β sheet. These combine to form a cleft with two α helices running along the edges, a β sheet as the floor and the peptide bound in the middle, like a hot dog in a bun. This structure is quite robust. All the class I protein structures are very similar. The overall structure is independent of the allele or peptide bound. While the primary amino acid sequences of different class I molecules can differ by up to 30%, and they have completely unrelated peptides bound, the α carbon backbones are nearly identical. Surprisingly, the peptide, which provides much of the specificity of interaction with CD8 T cells, is largely buried in the structure with only a few atoms directly accessible to the T cell receptor.

Genetics of class I genes

Polymorphism

Many genes are polymorphic. Different individuals in a species have distinct sequence variants in the coding sequences of expressed genes. Class I genes are uniquely polymorphic in two regards. First, the sequences of alleles differ not by the common one or two amino acids, but by as much as 30% of their amino acids. Secondly, while most polymorphic loci have a few major alleles found at high frequency and variants found at low frequency, class I genes have a much larger number of alleles. Indeed, a new class I allele is found in almost every new mouse population which has been sampled. More than 100 distinct class I genes have been described in mice.

It has been suggested by many investigators that this polymorphism, which is a prominent feature of class I genes, is crucial to its function in resistance to

infectious disease. Thus the existence of many alleles confers on the species the ability to survive the introduction of new pathogens, since it is likely that at least one of the class I genes will be able to bind and present peptide from the new pathogen to T cells and that individual would be able to mount a protective immune response. Thus this polymorphism provides a great evolutionary advantage to species which possess it. **Figure 1** shows the structure of the K^b molecule with the vesicular stomatitis virus 8mer (RGYVYQGL) bound. The polymorphic residues in each domain are highlighted. As can be seen, they are not randomly distributed throughout the protein. They are clustered in the region that is necessary for peptide binding.

In contrast to the K, D and L genes, the remainder of the class I genes are much less polymorphic in sequence. Thus the sequence similarity among Tla and Qa genes from different mouse strains is limited to a small number of changes, which are found only rarely.

Gene structure

All class I genes share a similar organization in genomic DNA. They are composed of eight exons. The encode the cleaved leader sequence, two exons which comprise the peptide-binding domain (see Structure), a third extracellular domain which binds β_2 -microglobulin and five small exons which comprise the transmembrane and intracellular portions of the molecule.

Gene mapping

The majority of class I genes are located in a cluster on chromosome 17, at about 20 cM. This region has been extensively studied and physical maps have been derived from cosmid cloning of this region. The K and D genes flank the class I and class II regions. The Tl and Qa regions are located centromeric from the classical class I genes, with the Qa genes close to D. It is of interest that the sequences of the genes in the Qa and TL regions are conserved, but it is the organization and number of genes that varies among different inbred strains of mice rather than the sequences of the genes. One other class I-related gene deserves special mention: the CD1 genes map on chromosome 3, at 48 cM. This small gene family (four genes) is related in both sequence and function to the classical class I genes, and may be involved in antigen presentation of nonpeptide epitopes to T cells.

Figure 1 (A) Ribbon diagrams of the K^α molecule with the vesicular stomatitis virus 8mer (RGYVYQGL) bound. Polymorphic residues in the α1 domain (exon 2) are highlighted in blue, α2 (exon 3) in red, and α3 (exon 4) in purple. (A) T cell receptor view of the complex. (See also color **Plate 8A**.)

Function of class I proteins

The major function of the K, D and L class I proteins is to bind peptides produced inside the cell and to display them on the cell surface for inspection by the immune system. The result of this display of a new peptide/class I complex on the cell surface is the recognition of the complex by CD8⁺ cytotoxic T cells. This interaction results in the destruction of the cell expressing the complex. In a sense, expression of a virus-derived peptide by a cell is a 'KILL ME' sign. As a result, it is important that only the cells expressing the viral protein express the peptide on the cell surface. This has resulted in a mechanism in which the binding of the peptide to the class I protein is integral to its biosynthesis and assembly in the endoplasmic reticulum. The exchange between class I molecules on different cells is therefore minimized.

Synthesis and assembly of class I

MHC class I molecules are trimers with a single invariant light chain, β₂-microglobulin, which is complexed with the polymorphic K, D or L proteins and a peptide. On any given cell, many different peptides are bound to each kind of class I molecule, but only one peptide is found in each β₂-microglobulin K/D/L peptide trimer. Further, each cell will express a K, D and L molecule from each parent. Thus there is an array of different molecules on the cell surface. It is important to emphasize the relative lack of interchange of peptides on class I molecules. If there was rapid exchange of peptide between class I molecules on different cells, it could result in destruction of uninfected bystander cells which would be dangerous to the host during the immune response.

Class I heavy chains and β₂-microglobulin are syn-

Figure 1 (B) side view of the molecule. (See also color **Plate 8B**.)

thesized on ribosomes of the rough endoplasmic reticulum (ER) and are cotranslationally inserted into the lumen of the ER (**Figure 2**). There, they associate on the peptide-loading complex. The newly synthesized class I heavy chain first binds the chaperone, calreticulin. The complex then moves to the peptide-loading complex. This complex is composed of the peptide transporters TAP1, TAP2 and tapasin.

TAP1 and TAP2 are members of the ABC (ATP-binding cassette) transporter family. Association with this complex is required for efficient loading of peptides on to class I. Only when peptide is assembled into the K/D/L β_2 -microglobulin complex does the molecule achieve its final and stable conformation. It is then released, transferred to the Golgi complex and exported to the cell surface.

Figure 2 Pathway of class I assembly inside the cell. In the absence of the molecular interactions shown, minor pathways can be detected. The change in the shape of the heavy chain denotes a change in the molecule detectable by monoclonal antibody. (Drawn by Dr Amy Peace-Brewer, University of North Carolina.)

Specificity of peptide binding to class I

Class I molecules must be able to bind peptides with a variety of sequences. Thus, the binding must lack the exquisite specificity of antibodies. At the same time we know from biochemical binding experiments that binding is limited. These molecules utilize specific interactions with specific amino acids called anchor residues, as well as contacts with other atoms in the peptide. The anchor residues differ among the different K/D/L proteins, both in the position of interaction of the peptide and in the amino acid in the anchor position. For example K^k binds glutamic acid at position 2 and isoleucine at position 8, while K^d binds tyrosine at position 2 and leucine at position 9. Thus different K alleles will bind different sets of peptides, as will different D and L alleles. This maximizes the possibility that any virus will have at least one peptide that can be productively presented to the immune system.

The class Ib molecules appear to have distinct binding characteristics. For example, the M locus products bind peptides with N-formyl methionine as the N-terminus, suggesting a role in the presentation of peptides derived from intracellular bacteria. Some

CD1 proteins may present nonpeptide epitopes derived from cell membranes and cell walls of *Mycobacteria* to γδ T cells. The specificity of other class Ib molecules is unknown.

Transplantation

A consequence of recognition of class I proteins with virus peptides bound is that the immune system recognizes different alleles with considerable vigor. Class I proteins that differ in sequence bind different sets of peptides, but importantly are recognized by large numbers of T cells. The requirements for allorecognition are still a matter of debate, but clearly T cells which recognize allogeneic MHC bound to a specific peptide and those which are indifferent to the bound peptide both exist. The consequences of the recognition are profound. Mice that differ only in a single class I product, either by production of a transgenic line or by spontaneous mutation are able to mount rapid and effective graft rejection. The cellular mechanism of rejection involves both CD4 and CD8 T cells, and results in rapid organ graft rejection.

Mating preferences

Class I alleles also affect mating preferences. A female mouse will consistently choose to mate with males whose class I differs from her own. This has also been shown in large breeding experiments in experiments that mimic natural environments. While the exact mechanism for this is unknown, it appears to relate to odors learned in the nest. Mice can distinguish odors associated with urine whose donors differ only in the class I genes. It is also interesting that exposure of pregnant females to urine from MHC-different males results in resorption of the embryos. There is much speculation that these mechanisms may help to contribute to the maintenance of polymorphism at the population level at times when selection by pathogens is not occurring.

H2 CLASS II

Gail A Bishop, Departments of Microbiology and Internal Medicine, The University of Iowa, Iowa City, Iowa, USA

The class II molecules encoded by the mouse major histocompatibility complex, H2, have as their predominant role, the binding and presentation of antigenic peptides for recognition by the antigen receptor complex of the T lymphocyte. They thus play a crucial role in self–nonself discrimination by the immune system. The development of recombinant inbred strains of mice by George Snell and others allowed the genetic mapping of class II genes, as well as many subsequent experiments performed by a large number of laboratories, which have revealed how class II molecules function to regulate immune responses. H2 class II molecules have now been shown to play critical roles in antigen presentation, which in turn affects both the activation of mature T lymphocytes as well as T cell development and selection. Studies of class II knockout mice have revealed a variety of defects in the immune response

which result from a lack of cell surface class II molecules. Although less well studied, class II molecules have also been suggested as playing a role in signal transduction to cells which express them.

Discovery of H2 class II molecules

In the mid- to late 1960s, a number of investigators reported the observation that when lymphocytes from genetically disparate individuals were mixed together, small ‘resting’ lymphocytes began to transform into large blast cells and divide. This phenomenon was termed the mixed lymphocyte reaction (MLR). Serologically defined determinants encoded by H2 genes, and shown previously to control allograft rejection in mice, were found to correlate with responsiveness in an MLR, although not all serologically detectable H2 antigens were found to stimulate

the MLR. It was subsequently shown, using recombinant inbred mouse strains, that MLR responses mapped to a specific region of the H2 complex, separate from those loci which encoded class I major histocompatibility complex (MHC) molecules.

Additional evidence for the existence of the genes now known as class II came from a variety of studies which showed that the effectiveness of the immune response to certain pathogens appeared to have a genetic component. The increasing availability of inbred, genetically defined strains of laboratory animals, such as mice and guinea pigs, coupled with the use of defined synthetic polypeptides as antigens allowed researchers to dissect the basis for these observations. During the course of these studies, the genes controlling these immune responses were dubbed 'immune response' or Ir genes. The use of recombinant and congenic inbred mice allowed the mapping of Ir genes to the middle of the H2 complex. It was concluded that responses to soluble protein antigens and the MLR are regulated by these Ir genes, which mapped to a distinct location from then known H2 loci controlling allograft responses. It was thus suggested by Jan Klein in the late 1970s that MHC molecules controlling the different responses be referred to as class II and class I, respectively – the designation which is now used.

Genetic organization of the H2 class II region

The region of the mouse H2 complex containing the class II genes was historically called the 'I' region, as it contains the aforementioned Ir genes, and the molecules encoded by these genes are called Ia antigens. The two classical class II antigens produced by the H2 complex are I-A and I-E. A current map of the class II region is shown in Figure 1. In addition to the genes which encode known functional class II molecules ($A\beta$, $A\alpha$, $E\beta$ and $E\alpha$), there are four additional class II genes (Pb, Oa, Ob and $E\beta 2$) whose function is not yet clear. Although Pb appears to be a pseudogene, transcripts from the Oa, Ob and $E\beta 2$ genes have been found. The Oa and Ob genes produce a nonpolymorphic, serologically recognized molecule with an expression pattern distinct from that of the classical H2 A and E molecules. That is, the H2 O molecules are expressed in spleen and

lymph node follicles, but only in B cell-rich areas, suggesting H2 O is not expressed by macrophages and dendritic cells. H2 O is also found in thymus, but restricted to a population of medullary epithelial cells which are virtually negative for H2 A and E expression. However, the functional role of the H2 O molecule remains elusive. The region between the Oa and Ob genes contains genes which encode proteasomal subunits (LMP1 and LMP2), the peptide transporters for class I molecules (TAP1 and TAP2), and the three H2M genes whose products are involved in proper association of class II with antigenic peptides (Ma, Mb1 and Mb2).

One of the great advantages which the mouse as an experimental animal has provided to the study of the structure and function of the MHC is the availability of a wide variety of H2 recombinant mouse strains. Over 60 such strains were made by several laboratories and quickly made available to the scientific community. Knowledge of the MHC complexes of other organisms has not been achieved as rapidly due to the paucity of such intra-MHC recombinants. The study of H2 recombinants in the I region has revealed a 'hot spot' for recombination events within part of a large intron between exons 2 and 3 of the $E\beta$ gene. Comparisons of intra-MHC recombinant strains show a much higher degree of polymorphism to the left of this hot spot, i.e., from the 5' end of $E\beta$ through the $A\alpha$ and $A\beta$ genes.

Gene structure and polymorphism of H2 class II molecules

Mouse class II genes contain 4–5 exons (Figure 2). The first exon encodes the leader peptide, and the second and third encode the external domains of each chain. In β chain genes, the fourth exon encodes the connecting peptide and the transmembrane

Figure 1 Genetic organization of the H2 class II region. Genes of known function are represented by filled rectangles.

Figure 2 Gene structure of H2 class II I-A chains. Because of their chromosomal position, β and α genes are transcribed in opposite direction. Filled boxes represent exons; the exon number is above each. Portions of the mature class II protein which each exon encodes are indicated below the exon. L, leader peptide; $\alpha 1$, $\alpha 2$, $\beta 1$ and $\beta 2$ encode the external domains; CP, connecting peptide; TM, transmembrane domain; CY, cytoplasmic domain; UT, untranslated region.

domain, the fifth exon encodes the cytoplasmic domain, and the final exon encodes the 3' untranslated (UT) region. The α chain gene structure is similar, except that the fourth exon encodes the connecting peptide, transmembrane and cytoplasmic domains, as well as part of the 3' UT region.

H2 class II genes exist in a number of allelic forms, many of which have been cloned and sequenced. Sequence information reveals that there is extensive polymorphism at the nucleotide level, with the highest variability clustered in several short stretches of protein sequence in the first external protein domain of the A β , E β and A α genes, while there is little variability between alleles of E α . Most of the predicted amino acid substitutions encoded by these polymorphisms are nonconservative, and are in parts of the class II molecule predicted to form the binding pocket for antigenic peptides. Such variable amino acids can thus alter interactions with peptide, the T cell antigen receptor, or both.

The use of X-ray crystallography, together with chromatography techniques allowing the isolation and characterization of peptides bound in the class II binding pocket, has led to considerable current understanding of the structural constraints regulating class II-peptide interactions. In contrast to the peptide-binding groove of class I MHC molecules, the class II groove is open at both ends. This allows bound peptides to extend beyond the ends of the groove, and accounts for the greater average length and length variation of class II-binding peptides. However, although class II peptides can vary from 12 to 24 amino acids in length, class II molecules form many bonds with both the peptide main chain and side-chains, increasing binding affinity and potentially leading to similar conformation of peptides bound in the groove, despite differences in length and sequence. It is the side-chain contacts which show greatest variation among class II alleles, leading to allele-specific peptide sequence 'motifs'.

Expression of H2 class II genes and molecules

In contrast to class I molecules, class II molecules are expressed constitutively on only a limited number of cell types in the immune system. These include B lymphocytes, thymic epithelium, dendritic cells, and cells of the monocyte/macrophage lineage, including

Langerhans cells and hepatic Kupffer cells. While human HLA class II molecules are also found on activated T lymphocytes, this is not the case for mouse H2 class II molecules. A variety of stimuli can increase class II expression on these cell types, as well as induce class II expression on cell types such as fibroblasts, endothelial cells, and cells of the nervous system, which do not constitutively express detectable class II. B cell class II expression is enhanced by the lymphokines interleukin 4 (IL-4), IL-10 and interferon γ (IFN γ), as well as signals through the B cell antigen receptor complex and a number of microbial products. IFN γ also upregulates class II expression on macrophages and a number of cell types of nonhematopoietic origin. Additional cytokines and microbes and their products can also regulate class II expression in these cell types.

There is evidence for both transcriptional and post-transcriptional regulation of H2 class II gene expression, but it seems clear that the majority of regulation of amounts of class II protein occurs at the level of transcription. Thus, in a given cell population, the level of surface class II protein correlates closely with the level of class II mRNA. Most of the studies performed to date on detailed molecular mechanisms of control of class II gene transcription have focused upon human HLA class II genes. However, general principles appear also to apply to H2 class II gene expression in the mouse. Those studies which specifically examined control of mouse class II have focused primarily on control of α chain gene expression. The promoter region of the A α gene contains several *cis* regulatory elements located between 40 and 160 base pairs upstream of the transcriptional start site. These include the Y box (a 10 bp motif which contains a reverse CCAAT sequence), the X box (a 14 bp motif located adjacent to a palindromic regulatory element known as a cAMP response element or CRE), a 7 bp motif called the H box, and an element downstream of the Y box called the T box. The location of several of these elements is shown in Figure 3. Mutation or deletion of the H, X or Y boxes reduces both constitutive and IFN γ -induced class II expression in B cells. Additional experiments suggest that the X and Y boxes are also critical for expression of E α and E β .

It has been demonstrated that the X and Y boxes are recognition sites for DNA-binding proteins. A protein named NF-Y, which is ubiquitously

Figure 3 H2 A α promoter sequence. Positions of H, X1 and Y boxes are indicated by underlining. The X2 (CRE) element is indicated by boldface type.

expressed in all tissue types, recognizes the sequence CCAAT contained in the Y box of H2 class II genes, and consists of a heterodimer of two subunits, NF-YA and NF-YB. A protein called mXBP binds the A α X box sequence, and contains both a leucine zipper motif and a basic domain likely to bind DNA. mXBP binds as a homodimer to the A α CRE element, also called the X2 box, and can also form a heterodimer with the transcription factor c-Jun and induce its binding to CRE elements. As some of the stimuli which induce class II expression involve CRE motifs (e.g. engagement of the B cell antigen receptor), mXBP may play an important role in this induced expression.

Assembly, transport and peptide loading of class II molecules

The assembly of class II molecules occurs in the endoplasmic reticulum. The first event in this process is trimerization of the invariant chain (Ii) with which intracellular class II associates. Immediately after formation, this trimer associates with a pair of α and β chains, and two more heterodimers subsequently associate, to form a nonameric complex (Figure 4).

The chaperones immunoglobulin-binding protein (BiP) and calnexin enhance this process. The nonamers then travel across the Golgi and *trans*-Golgi to endosomal compartments. The nonameric complexes are unable to bind peptides, and there is strong experimental evidence that Ii plays an important role in preventing this association. Two different sequence motifs present in the Ii cytoplasmic domain have been shown to contribute to endosomal transport of class II, but Ii-independent transport has also been shown to occur. Sequences within the cytoplasmic domains of class II molecules themselves have been implicated in the regulation of Ii-independent transport.

Following endosomal localization, Ii is degraded by aspartic and thiol proteases into a nested set of peptides spanning Ii residues 81–104. These peptides are termed CLIPs. CLIPs associate with the peptide-binding groove of $\alpha\beta$ heterodimers, blocking their association with antigenic peptides. Removal of the CLIP peptides, which must precede normal class II peptide loading, is enhanced by the products of the H2M locus (see Figure 1). Recent evidence shows that these molecules directly promote CLIP release, as well as the release of peptides which bind class

Figure 4 Class II assembly and transport to the cell membrane. Details of the process are described in the text.

II relatively weakly. Antigenic peptides which bind tightly are not susceptible to this enhanced release. The specific nature of the endosomal compartment where class II associates with exogenously derived antigenic peptides is not completely defined. A large body of evidence indicates that peptide association and CLIP dissociation is favored by an acidic environment, such as that found in late endosomes and lysosomes. However, data from a large number of studies suggest that class II molecules are found to some extent at many levels in the endocytic system. Several studies have also suggested the existence of a specialized class II-containing compartment, distinct from previously characterized endosomal/lysosomal compartments, called the MIIC. MIICs show a multilamellar structure and contain lysosomal enzymes; this compartment may have a specialized role in class II antigen presentation.

Functions of H2 class II molecules

Study of the class II molecules of the mouse MHC has provided a great deal of the current information on the functional roles played by class II molecules in the immune system. Genetic manipulations which are feasible in defined inbred mouse strains have allowed investigators to examine in great detail how class II molecules regulate responses to antigen. The advent of transgenic and knockout mouse technology in more recent years has created additional opportunities for studying the roles of class II molecules, in both immune system development and function. Following the development of inbred, genetically defined strains of rodents, it was observed that the allelic forms of class II molecules expressed by an animal determine its responsiveness to certain soluble antigens. In fact, it was this property of mouse class II genes which was the basis for their early designation as immune response (Ir) genes. However, it was not until decades later that details of how class II molecules exert this regulatory effect were understood.

A major advance in this understanding occurred in the early 1980s, with two major discoveries, each involving the contributions of many investigators. The isolation and characterization of the T cell antigen receptor (TCR) in 1983–1984 demonstrated that the same receptor recognizes both antigen and MHC molecules on an antigen-presenting cell (APC). This implied that antigen must physically associate with MHC molecules to be recognized by a T cell. The subsequent discovery (1985–1987) that purified MHC molecules bind tightly to antigenic peptides in an allele-specific manner revealed the nature of the critical role of MHC molecules in antigen presen-

tation. In subsequent years, the peptide-binding sites of both class I and class II MHC molecules have been crystallized, and physical characteristics of these binding sites determined.

The ability to bind antigenic peptides and present them to T cells endows class II molecules with their major functional role – to effect the selection and stimulation of T cells by delivering signals through the T cell antigen receptor complex. The study of transgenic and knockout mice has revealed that when and where class II molecules are expressed during development of the immune system profoundly affects the development of T cell populations and the T cell antigen receptor repertoire. Class II thus plays a pivotal role in the ability of T cells to distinguish self from nonself and to react appropriately to antigen stimulation. It is not surprising, therefore, that the expression and peptide-binding properties of particular allelic forms of class II molecules are also implicated in the development of some autoimmune diseases. In the mouse, H2 class II molecules have been shown to play important roles in the development of experimental models of insulin-dependent diabetes, autoimmune encephalitis, collagen-induced arthritis and a murine form of lupus nephritis, among others. Conversely, a lack of class II expression from the earliest stages of development results in profound defects in the development of CD4⁺ helper T cells and in both cellular and humoral responses.

Class II molecules have also been shown to deliver signals to cells which constitutively express them, such as B cells and monocytes. Ligation of class II molecules on mouse B cells *in vitro*, alone or in combination with ligation of the B cell antigen receptor, can induce or enhance cell proliferation, antibody secretion, homotypic adhesion and IL-6 production. The molecular events involved in this signaling pathway are not well defined, but evidence has been presented for the involvement of both tyrosine and serine/threonine kinases, and the elevation of intracellular cAMP. Class II signals have also been shown to enhance signals delivered via the B cell receptor, CD40. It is not yet clear what role such signals might play in the regulation of *in vivo* immune responses, but recent *in vivo* studies in tumor immunity and using class II knockout mice have suggested that class II signals may affect the efficiency of antigen presentation by APCs.

H2 CLASS III REGION

Torben Lund, Department of Immunology, The Windeyer Institute for Medical Sciences, Division of Pathology, University College London Medical School, London, UK

The H2 class III region is located between the class II H2-Ea and the class I H2-D genes in the mouse major histocompatibility complex (MHC) on mouse chromosome 17 (Figure 1). Based on pulsed-field gel electrophoretic analysis and partial genomic cloning, the distance between H2-Ea and H2-D has been estimated to be 900 kb. Over 60 genes have been identified in the human MHC class III region, but although the cDNA clones for several of these genes detect unique cross-hybridizing sequences in the mouse H2 class III region, only a few of these genes have been identified as independent transcriptional units in the mouse. The class III region genes in the mouse, the rat and the swine MHC are organized similarly to those in the human HLA, suggesting an interspecies conservatism in the MHC class III region. There are, however, some differences between the HLA and H2 class III region, because the distance between Bat1 and H2-D is only 6 kb, whereas the distance between the homologous genes in the human MHC is 200 kb.

It has not been established if the HLA genes identified within this 200 kb have mouse homologs mapping within the H2.

H2 class III genes

The proto-oncogene *Int3* is located approximately 200 kb telomeric from H2-Ea. *Int3* is a member of the mouse Notch receptor family which all transduce proliferative signals by directly interacting with the DNA-binding protein RBP-J kappa. The *Int3* locus is a target for integration of mouse mammary tumor viruses, which are frequently associated with primary mouse mammary tumors. Such tumors contain a truncated transcript containing the whole intracellular part of the *Int3* product. Analysis of transgenic mice containing the tumor-specific truncated forms of *Int3* suggest that deregulation of the *Int3* gene in the mammary epithelial cells limits their capacity to perform apoptotic decisions.

Figure 1 Mouse H2 class III region. The relative map location of the putative genes G9, G9a and G10, and of G13, G14 and G15, has yet to be confirmed.

Pbx2 encodes a protein which, together with PBX1 and PBX3, is a member of a new family of homeodomain proteins. In common with PBX1, PBX2 binds cooperatively to DNA with the Hox gene products HOXB-7 and HOXB-8. While it is known that PBX1 is involved in transcription activation in leukemia, the function of PBX2 is not clear. However, when fused with E2a all members of the PBX family can transform mouse fibroblasts, suggesting that PBX2 may have a latent oncogenic potential. The human genome contains three different Pbx2 genes located on chromosome 1, chromosome 3 and chromosome 6 respectively, however only the single Pbx2 gene mapping in the H2 class III region is found in the mouse genome.

Pbx2 is linked to Rage which encodes a 65 kDa transmembrane cell surface member of the immunoglobulin superfamily expressed on monocytes and endothelial cells. The Rage product associates with a lactoferrin-like protein to form a receptor that can interact with advanced glycation end-product (AGE)-modified proteins and induce the synthesis and release of a range of inflammatory cytokines. The advanced glycation end-product is a nonenzymatic modification of proteins, nucleic acids and lipids exposed extensively to reducing sugars. The AGE products are very resistant to proteolysis and accumulate as a consequence of aging. Since diabetes is associated with hyperglycemia, AGE-modified proteins accumulate more rapidly in the later stages of the disease, where they have been implicated in various pathological complications associated with diabetes. The Rage products have also recently been implicated in the pathogenesis of Alzheimer's disease.

Tnx encodes an extracellular matrix protein, tenascin X, which has been implicated in the formation of heart, muscles and limb. Tenascin X belongs to a family of matrix proteins, the other members of which are tenascin C (also called tenascin or cytactin) and tenascin R (also called restrictin). Tnx appears to have at least three promoter sequences, of which the most upstream overlaps with the promoter for a newly identified gene G13/Creb-re, which in humans is transcribed in the opposite orientation to the Tnx gene. The Tnx gene spans about 100 kb and overlaps in the 3' end with the Cyp21 gene. The 160 kb containing the human Creb-re/CYP-21 segment has at least 13 different transcriptional units, including several that overlap in the same orientation (Z within C4, P450c21 within Y, XB-S within XB) and in the opposite orientation (XA, XB-S and XB within P450c21). The segment appears to be conserved in rodents (and also in cattle) and thus may contain the same genes; how-

ever, the mRNA for the individual transcriptional units has not been identified in the mouse.

G13/Creb-re (cAMP-responsive element-binding protein-related protein) is a member of the Creb/ATF gene family and encodes a leucine zipper protein. The gene has a very broad expression pattern and is supposed to encode a general transcription factor.

The region between H2-Ea and Cyp21a1 contains, in addition to the genes listed above, the sequences cross-hybridizing with the cDNAs for the human genes encoding G18, located between Int3 and Pbx2, and G16, G15 and G14 located between Rage and Tnx.

C4 gene encodes the fourth component of the mouse complement system. Two different allelic forms of the C4 gene have been detected, characterized by high (C4^h) and low (C4^l) levels of expression. The Slp (sex-limited protein) gene shows structural similarities with the C4 gene, exhibits EDTA-independent complement activity and is expressed in the liver. In contrast to the C4 product, which is present in all mouse strains analyzed, Slp is only present in male mice with high C4 expression. Female expression has been noted in a few strains such as FM, PL/J and NZB mice, but is, in these strains, regulated by non-H2-encoded RIs (regulator of sex limitation) genes. In addition, the Slp gene in some wildtype haplotypes (H2^{w7}, H2^{w16}, and H2^{w19}) is constitutively expressed in both male and females, and the haplotypes contain several copies of C4 and Slp. Genetic analysis of these haplotypes have shown that the constitutive expression is caused by three copies of hybrid genes where the 5' part of the C4 gene is fused with the 3' part of the Slp gene, resulting in a hybrid gene regulated as the C4 gene.

Linked to the 3' end of both the C4 and Slp gene are the Cyp21a1 and Cyp21a2, respectively. Whilst Cyp21a1 is a pseudogene, Cyp21a2 encodes the steroid 21-hydroxylase which is expressed in the adrenal glands. This enzyme is involved in the biosynthesis of both cortisol and aldosterone. The linkage of the Cyp21 genes with C4 and Slp is conserved between the species and would suggest an early duplication of ancestral C4 and Cyp21 genes linked together.

The C2 and Bf genes are structurally and functionally related. Both genes encode soluble proteins involved in the classical complement activation pathway (C2) or alternative complement pathway (Bf). Both genes show very limited genetic polymorphism. Between Slp and Bf is the RD gene encoding a 44 kDa nuclear protein containing 24 tandem repeats of arginine and aspartic acid/glutamic acid dipeptides. The function of this gene has not yet been established.

The region between C2 and H2-D contains several

sequences related to the human HLA class III region genes; however, only a few of these have been analyzed at the transcriptional level. The MHC class III region contains three members of the heat shock 70 family, Hsp70-1/Hsp70-3/Hsc70-t, where Hsp70-1 and Hsp70-3 are two tandem heat-inducible genes and the expression of Hsc70-t is confined to the male germ cells. These genes are centromeric to the G7a gene that in humans encodes valyl-tRNA synthetase.

B144 (equivalent to HLA-gene LST-1) is preferentially expressed in B cells and macrophages. Although the function of the gene product has not been established, the expression pattern suggests a function for the B144 gene product in the immune response.

Centromeric to H2-D is the Tnf cluster containing genes for tumor necrosis factor α (Tnf), lymphotoxin α (Lta) and lymphotoxin β (Ltb). Both TNF α and LT α have multiple functions in the immune response and are expressed in a variety of tissues. Both cytokines can be expressed as a membrane-anchored and as a secreted protein. The membrane attached LT α forms a heterodimer with the structurally related LT β encoded by Ltb. The LT α -LT β complex is a ligand for the LT β receptor and is expressed early in the embryo, where it is involved in the development of the lymph node and splenic architecture. The LT α -LT β heterodimer is also important for the formation of germinal centers.

The region between Tnfb and H2-D contains two genes encoding nuclear proteins, I κ BL and BAT1. I κ BL encodes a protein structurally related to NF κ B, whereas the product of the BAT1 gene product is a member of the RNA hexicase superfamily with homology to the rat P47 nuclear protein and the WM6 gene of *Drosophila*.

Disease susceptibility

Several diseases have susceptibility genes mapping to the MHC. Although many of these involve specific alleles for the MHC class I and class II molecules, others have susceptibility genes mapped to the MHC class III region. In some instances, where there exist mouse models, inbred intra-MHC recombinant mouse strains with recombinant breakpoints in the MHC class III region have helped to map the genetic trait to the region between the C2 and Tnf gene clusters. In this region is the locus that controls the hematoopoietic histocompatibility antigen, Hh-1, the gene

that affects antibody responses to TNP-Ficoll, and the neuraminidase locus which has been identified as G9a in the human MHC. In addition the cortisone-induced cleft palate susceptibility gene, Cps-1, has been located between the Hsp70 cluster and G7a encoding valyl-tRNA synthetase. In this region is also the locus that determines susceptibility to experimental autoimmune orchitis, Orch-1.

Characteristics of the organism and its antigens

Haemophilus influenzae is a gram-negative pleomorphic bacterium whose only ecological niche is the human host. While the primary residence of this human pathogen is the upper respiratory mucosal epithelium, it can invade these surfaces and cause serious systemic disease. An important virulence factor associated with *H. influenzae* is its capsular polysaccharide. The presence of this structure divides the species into encapsulated and nonencapsulated strains. Six different capsular serotypes have been described. *H. influenzae* serotype b (Hib), whose capsule is a repeating polymer of polyribosyl-ribitol phosphate (PRP), have accounted for the majority of invasive disease caused by *H. influenzae* until the recent widespread use of conjugate vaccines. Hib strains represent a clonal population. In contrast to Hib, nonencapsulated or nontypeable *H. influenzae* (NTHI) are a genetically and antigenically diverse group of organisms consisting of numerous clonotypes.

Encapsulated and nonencapsulated *H. influenzae* express other outer membrane surface structures, including fimbriae, lipooligosaccharides (LOS) and outer membrane proteins (OMPs), which are important in colonization of the human host and in pathogenesis of infection. Because of the clonal nature of the Hib strains, the surface antigens are relatively conserved among strains. By contrast, a characteristic feature of NTHI strains is the antigenic heterogeneity of surface antigens among strains. Two of the most abundant surface antigens are LOS and OMP P2, which comprises approximately half of the protein content of the outer membrane. These two molecules demonstrate striking heterogeneity among strains, particularly in the regions of the molecules, which are exposed on the bacterial cell surface.

H. influenzae colonizes the human upper respiratory tract. Almost all of the colonizing strains are NTHI. Colonization by NTHI begins early in childhood and continues through adult life. Analysis of prospectively recovered strains has shown that colonization by NTHI is a dynamic process; children eliminate strains and acquire new strains of NTHI frequently. Colonization with NTHI at an early age

is associated with an increased incidence of otitis media in children. Whether nasopharyngeal colonization is an immunizing process is not yet known.

The most serious systemic disease caused by *H. influenzae* is meningitis. The incidence of invasive Hib disease, particularly meningitis, has decreased dramatically since the mid-1980s. This decrease is due to the widespread use of vaccines which are composed of Hib polysaccharide capsule conjugated to protein carriers. While Hib causes invasive infections, NTHI causes predominantly mucosal infections. NTHI causes 25–30% of all cases of otitis media. Approximately 80% of all children will experience at least one episode of otitis media by the age of 3 years. NTHI is a common cause of lower respiratory tract infections in adults with chronic obstructive pulmonary disease. More recently, NTHI has been recognized as an important cause of pneumonia in adults with acquired immune deficiency syndrome (AIDS) and in children in developing countries. The incidence of invasive disease caused by NTHI strains is increasing. The conjugate vaccines are not effective in preventing disease caused by NTHI strains.

Immune responses of the host

In the 1930s, Fothergill and Wright demonstrated that serum bactericidal activity to Hib was associated with protection from infection. Subsequent work in animal models and human systems has established that much of this bactericidal activity is mediated by antibody to capsule and that antibody to the PRP polysaccharide capsule protects against invasive infection. These observations guided work on vaccine development in the 1970s and 1980s.

By the age of 3 years, most children have acquired natural antibodies to PRP. Children with invasive Hib infection have low levels or no detectable anticapsular antibody at the onset of infection. Even in the convalescent period, the titers of anticapsular antibodies in children remain low until approximately 2 years of age. These children are susceptible to reinfection and second and third episodes of Hib meningitis have occurred in the same child. The response to the PRP polysaccharide in children below

age 2 is typical of the response to a T-independent antigen.

Less is known about the host immune response to nontypeable strains of *H. influenzae*. A hallmark of infections caused by NTHI is the high rate of recurrences. Therefore, infection does not confer subsequent protection from infection by NTHI strains. Serum bactericidal antibody develops following otitis media due to NTHI and this antibody response is associated with protection. However, the immune response is specific for the infecting strain and the child remains susceptible to infection by other strains of NTHI. A similar scenario may occur with recurrent exacerbations of chronic obstructive pulmonary disease. The strain-specific immune response is directed at least in part to immunodominant surface epitopes on the P2 OMP. These observations regarding strain-specific immune responses may account for the observation that these apparently immunocompetent populations experience recurrent infections.

The LOS of *H. influenzae* is a major toxin associated with the species. There is a human humoral immune response to specific carbohydrate structures but little is known about the functional activity of this antibody. Recently, the *htrB* gene has been characterized in *H. influenzae*, *htrB* encodes for an acyltransferase which is responsible for the myristic acid substitution of *H. influenzae* lipid A. It has been shown that *htrB* mutants are less toxic than the parent strain from which they are derived, as they are less invasive in the rat nasal challenge model. In addition, *in situ* hybridization studies with primary human respiratory epithelial cells has shown that LOS from wild type *H. influenzae* generates a tumor necrosis factor α (TNF α) mRNA response that is ten-fold greater than LOS from *htrB* mutants.

Little is known about the mucosal immune response to NTHI. This is an important area of investigation because most infections caused by NTHI are mucosal infections.

Vaccines

The development of conjugate vaccines to prevent invasive infections by Hib represents a dramatic success in the prevention of an infectious disease. High concentrations of serum immunoglobulin G (IgG) to Hib capsular polysaccharide confer increased bactericidal and protective activity. PRP alone is a poor immunogen. Conjugating the PRP capsular polysaccharide to protein carriers has resulted in vaccine formulations which effectively induce protection from invasive Hib infections in infants. The antibody response to the vaccines is restricted. The predominant IgG subclass induced by vaccination is IgG1,

and the predominant IgG light chain expressed is V κ II α . Qualitative differences in antibody repertoires induced by natural exposure, purified PRP vaccine and each of the four conjugate vaccines have been observed. However, no major differences in protection afforded by the different vaccine formulations have been noted. Although antibody to PRP confers protection, an antibody concentration which correlates with protection cannot be precisely defined. Factors other than antibody concentration play a role in determining protection. These include avidity of antibodies and the priming effect of early vaccination with conjugates.

An unexpected but important effect of vaccination against Hib has been observed. Vaccinated children have a decreased incidence of nasopharyngeal colonization with Hib. This is probably one of the important mechanisms by which the vaccines prevent invasive infections.

The development of a vaccine to prevent infections caused by NTHI is the subject of intensive investigation. An approach has been to identify surface proteins which are relatively conserved among strains of NTHI and test these proteins for their ability to induce a protective immune response. Candidate antigens include P6, a 16 kDa OMP; P4, a 30 kDa OMP; fimbriae; high molecular weight adhesins; protein D; and others.

HAPTEN

Ilkka JT Seppälä and **Olli Mäkelä**, Department of Bacteriology and Immunology, University of Helsinki, Helsinki, Finland

Hapten is usually defined as a substance that is not immunogenic as such but can bind to antibodies of the appropriate specificity (hapten-specific antibodies). A hapten can be made immunogenic by coupling it to an immunogenic protein (the carrier). The conjugate is then immunogenic not only with respect to carrier epitopes but also to the hapten. 'Antigenic' is sometimes incorrectly used as a synonym for 'immunogenic', but free hapten is 'antigenic' and not 'immunogenic'. Antibodies specific to a hapten can only be raised when the hapten is foreign to the individual to be immunized.

Small haptens are widely used as defined antigenic determinants (epitopes) in basic immunology. Unlike natural epitopes of proteins, haptens can be easily handled in the laboratory both in the coupled and in the free form. They have helped immunologists to evaluate the specificity, affinity and heterogeneity of antibodies, and to estimate the size of their antigen combining site. Haptens were used to obtain the first X-ray crystallography pictures of antibody–antigen complexes. The concept of T cells helping B cells to produce antibodies is heavily based on the demonstration of B cell hapten recognition, coupled to carrier molecule recognition by T cells. Use of haptens enabled the analysis of inherited and acquired elements of the antibody response. Another aspect is the development of immunoassays to quantify many different molecules in body fluids or other solutions.

Some compounds have a borderline immunogenicity but are considerably stronger immunogens when linked to proteins. For example, the type b capsular polysaccharide of *Haemophilus influenzae* (Hib) is very weakly immunogenic when given to children aged 1 year or less, but a significant immun-

ogen when given to adults. When Hib is coupled to immunogenic proteins such as diphtheria toxoid, young children also produce a fair amount of Hib-specific antibodies in response to vaccination. Hib is thus a hapten in young children but an immunogen in adults.

Many haptens are small molecules (≤ 1 kDa), and as such nonimmunogenic. When coupled to a protein a small hapten can become an antigenic determinant (epitope). An epitope can, however, include the hapten plus an adjacent region of the carrier as well. Thus, unless excluded by specificity controls, monoclonal antibodies to haptens may be suspected of having some affinity preference to the hapten–amino acid conjugate, as it was presented in the immunogen, over free hapten.

Other haptens are macromolecules (>100 kDa). It is not completely understood why they are haptens rather than immunogens, but one factor is that coupling to immunogenic proteins brings T cell help to the antihapten response.

A growing interest centers on the generation of artificial epitopes of proteins. A common approach has been to prepare conjugates of peptides and carrier proteins. This has, however, often failed to reproduce the orientation of the peptide in the original protein, to the extent that the antibodies obtained have been irrelevant to the aimed task. Newer approaches have included incorporation of a nucleotide sequence coding for the peptide epitope into the gene for another protein. The insert is placed at a position that is known to produce a protruding loop on the surface of the expressed protein. Carrier genes found suitable include those for influenza virus, hemagglutinin, penicillinase, etc.

Preparation of hapten conjugates

Suitable attachment points on the carrier protein molecule are presented in Table 1. Usually, the hapten is modified to make it 'reactive'. Exceptional haptens, e.g. penicillin and its relatives, spontaneously convert to the active form. Commonly used, artificially introduced reactive groups are shown in Table 1. Proteins usually function well as carriers without modification, but sometimes they have been improved by the addition of reactive groups like thiol or hydrazide groups. These groups can be set at a defined distance from the carrier molecule through a spacer.

When peptides are used as haptens, hydroxyl (OH) groups of tyrosines or amino (NH₂) groups of lysines are usually used as the groundwork of the reactive group. Failures have sometimes been observed due to destruction of the epitope by the coupling, through incorrect folding of the peptide, or through lack of appropriate postsynthetic modification like amidation, as has been observed for some polypeptide hormones.

Special expertise in chemistry is required for derivatization of steroid hormones toxins, or drugs to forms that can be bound to carrier molecules in the correct orientation. Because of the high demand for antibodies to these substances, several tailored derivatizations of these compounds have been published.

Monitoring of hapten binding

Monitoring is carried out in basic immunology, usually to determine affinity of antibodies, and in clinical chemistry, forensic science, etc., to quantify substances of low concentration.

The gold standard for measuring the affinity of a hapten-specific antibody is equilibrium dialysis. It requires that the concentration of specific antibody is known and that the concentration of the hapten can be determined at the concentration range where half saturation of antigen-binding sites occurs (usually 10⁻⁶ M or less). Therefore, the hapten must

carry a tracer, usually a radioactive atom – often considered too laborious to prepare.

An alternative reference method for affinity measurement is fluorescence quenching. A part of tryptophan fluorescence emitted by antibody molecules is quenched when the combining site is occupied by the epitope (hapten). The maximum degree of quenching varies but in some monoclonal antibodies it can be up to 80% of the total fluorescence. Exposed tryptophan residues must then be almost exclusively located around the antigen-binding site. Also, affinities can already be measured when only 20–40% of the fluorescence is quenched by the hapten binding. With suitable instrumentation the association and dissociation reactions can be evaluated separately. In practice, the operating range extends to lower affinities than can be measured with equilibrium dialysis. Both methods described above give actual binding constants but are laborious to carry out.

When it suffices to determine relative affinities in a set of antibodies, less laborious methods are available. Free hapten inhibition of binding of a labeled hapten to antibody may then suffice. Another means for practical affinity measurement is based on surface plasmon resonance (for example using the BIA core™ machine produced by Pharmacia), essentially a method for detecting the mass of substances collected to a surface through change in the refractive index for light. Both association and dissociation reactions may be followed in real-time mode. Some disturbances by surface effects may be possible. Therefore, the affinities obtained are to some extent relative but comparison of reagents and detection of interactions can easily be done.

Many practical immunoassays (measurement of drugs, hormones, toxins, etc.) depend on hapten binding to an antibody. The simplest monitoring of hapten binding is carried out without separating bound and free hapten (homogeneous methods). For example, in the fluorescence polarization method, the hapten is coupled to fluorescein and exposed to

Table 1 Structures on carriers and haptens that participate in coupling

Structure on carrier	Active group in the hapten
Tyrosine	Azo
ε-Amino group of lysine	Azide, <i>N</i> -hydroxysuccinimide, phenylisothiocyanate, aldehyde (coupling of saccharides by reductive amination, etc.)
Carboxyl group of aspartic or glutamic acid	Amino group via carbodiimide
Free sulfhydryl group of cysteine or of SPDP [3-(2-pyridyldithio)-propionic acid <i>N</i> -hydroxysuccinimide] modified lysine	Maleimide

polarized light. When an antibody binds this hapten, the rotation of the fluorescein is inhibited and the emitted light is polarized. The unbound hapten-fluorescein complex rotates freely and emits unpolarized light.

In most immunoassays, the bound hapten is separated from the free hapten. The oldest method is the Farr type competitive immunoassay. The hapten is labeled and, after incubation, bound and free hapten are separated, usually by precipitation and centrifugation. When the concentration of the hapten is very low ($<10^{-10}$ M in the case of growth hormone), a very high-affinity antibody is needed for such an assay. Other separating immunoassays (e.g. the immunometric assays) are less dependent on antibody affinity. Since they are also less laborious than the Farr assay, they have largely replaced it.

Drugs as haptens in clinical medicine

Adverse reactions to drugs are sometimes due to interaction of the drug and antibody to it. In order for a drug to be immunogenic, either the drug itself or its metabolite must be capable of binding to a large molecule of the body, most commonly a protein. β -lactam antibiotics (e.g. penicillin) are an example. They form covalent bonds to proteins due to spontaneous breakage of the β -lactam ring and a concomitant emergence of a chemically reactive group. When sufficiently high doses are used, some molecules of the body are apparently modified by several bound β -lactam molecules. An immunogenic molecule is then formed. Immunoglobulin M (IgM) and IgG anti-penicilloyl seem to cause cytolytic reactions; IgE class antibodies have been observed in anaphylactic reactions and in drug-induced fever reactions.

Some drug reactions are immunologically mediated but antibodies are not involved. Sulfonamides and several anticonvulsants yield metabolites that have an active prosthetic group able to bind to protein. The target for the binding is usually a nearby protein at the site of the metabolic event. The protein to be modified is thus mostly the enzyme itself that catalyzes metabolite production. Hence, the cytochrome P450 group enzymes are a preferential target. The altered protein is believed to yield an altered

peptide which binds to the major histocompatibility complex (MHC) of the cell, creating a target for T cell attack. Susceptibility to this kind of reaction is determined by the MHC phenotype of the patient and apparently also by allelic variation in detoxifying enzymes such as epoxide hydrolase.

Drug reactions have been described which seem to have an immunological basis, but the drug appears to be unable to couple covalently. α -Methyldopa is an example. A hypersensitivity reaction to this drug causes formation of autoantibodies and a lupus-like syndrome. The drug may or may not act as a hapten in such cases; for example, it may act as an epitope for the T cell antigen receptor, and covalent coupling may then be unnecessary for immunogenicity. The drug might also bind to protein noncovalently and change its conformation. Some cases previously thought to operate in this way have been recently explained by covalent protein binding activity of the (often ill-defined) metabolites of the drug concerned.

HEAVY CHAIN DISEASES

Jean-Louis Preud'homme, Laboratory of Immunology and Immunopathology,
Central University Hospital, Poitiers, France

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Heavy chain (HC) diseases (HCD) are monoclonal immunoproliferative disorders characterized by the production of abnormally short immunoglobulin (Ig) HC without associated light chains (LCs). HCD are known for the three main Ig classes.

Clinical presentation and diagnosis

The clinical presentation usually varies according to the HC class. Apart from a very few cases exhibiting a respiratory disease, α -HCD, the most common HCD, usually affects young adults originating from areas with a high degree of infestation by intestinal microorganisms and having lived in conditions of poor hygiene. α -HCD is common in North Africa, the Middle East and southern Europe. It is also encountered in the Far East, southern Africa and Latin America. Patients usually present with a severe malabsorption syndrome due to a diffuse and massive infiltration of the small bowel and mesenteric lymph nodes, usually by mature plasma cells. More rarely, the proliferation is lymphoplasmacytic or lymphocytic. This first stage of the disease is possibly benign. It is susceptible to complete remission under oral antibiotics. The natural history is an evolution toward a malignant large cell lymphoma of the same clonal origin as the initial proliferation.

The clinicopathologic features of γ -HCD vary, with a lymphoplasmacytic proliferation similar to that of Waldenström's macroglobulinemia in 40% of cases and, in other cases, various forms of lymphoid proliferations, including lymphomas and chronic lymphocytic leukemia (CLL), or no detectable lymphoproliferative disorder. Association with autoimmune diseases is not uncommon. μ -HCD is rare. It presents with the same variety of immunoproliferative disorders as γ -HCD, typically CLL with vacuolated bone marrow plasma cells. Although truncated HCs (structurally different from HCD proteins) are able to deposit in tissues in amyloidosis and heavy chain deposition disease, there is no documented tissue deposition in HCD (a single case of amyloidosis of unknown composition was reported in γ -HCD).

Diagnosis is based upon the demonstration of monoclonal HCs without associated LCs by the immunochemical study of the serum (or of the intestinal fluid in certain cases of α -HCD without serum α -HCD protein). There is rarely a narrow band by

electrophoresis, HCD proteins being often heterogeneous in charge, especially α -HCD proteins which migrate from albumin to slow gammaglobulins in certain patients. μ -HCD proteins often migrate in the α -globulin region. Hence, HCD proteins may easily be missed. Immunoelectrophoresis can be either misleading (certain IgA λ fail to precipitate with anti-LC sera) or very useful, for example when using anti- α antisera containing antibodies to conformational epitopes of the Fab α region. The immunoselection method, a gel immunodiffusion technique in which anti-light chain antisera are included in the gel (thus preventing light chain-containing molecules migrating) can also be used as a diagnostic tool.

There is an HC subclass restriction, always α 1 in α -HCD and with γ 3 overrepresentation in γ -HCD. HCD proteins usually polymerize (except for certain γ -HCD proteins that are present in the serum as dimers) and are rarely present in significant amounts in urine. Free LCs that do not associate with HCs are produced in about 50% of μ -HCD cases, leading to urinary Bence Jones proteins. LC cast nephropathy was recently observed in such a case. Non-secreted cellular LCs are found in a few α - and γ -HCD cases. Nonsecretory forms occur in α -HCD, diagnosis being made at the intestinal plasma cell level. The clinicopathological picture of α -HCD is the same as that of the Mediterranean type or immunoproliferative small intestinal lymphoma (IPSID). Certain IPSID patients lack detectable α -HC in the serum and intestinal fluid. Nonsecretory α -HCD seems to account for only a minority of them.

Structural alterations of HCD proteins

Structural study of HCD proteins reveals normal carboxy-terminal regions and deletions involving the variable (V) region and most often the first constant (C_{H1}) domain (Figure 1). The normal sequence usually resumes at the beginning of the hinge region or of a C_{H1} domain. Comparison of the available sequence data shows four situations:

1. A few μ -HCD proteins lack the V domain only.
2. The absence of V and C_{H1} (and in one instance C_{H2}) domains is a feature of some α - and γ -HCD proteins. However, in such a case (Omm), the cellular HC precursor contained a normal leader (L) peptide and 15 residues from the V

Table 1 HCD genes

	<i>V region</i>			<i>Switch/C_H1 region</i>		<i>Remainder of the C region</i>
	<i>L-V intron</i>	<i>VDJ exon</i>	<i>VDJ 3' flank</i>	<i>5' to switch</i>	<i>3' to switch</i>	
μ -BW	Normal	1 bp deletion in V generating stop codons	A 138 bp deletion 3' to J4 with a 51 bp insertion (3' splice site of VDJ4 deleted)	NS	C _H 1 normal	Normal
γ_3 -Omm	Normal	A 320 bp internal deletion at V-J4 junction	Mutations, deletions, and a 37 bp duplication in the J4-J5 IVS	Normal?	A large deletion from switch to C _H 1 leaves its 3' end	Normal
γ_1 -Riv	A 80 bp deletion with 56 bp insertion (V 5' splice site deleted)	A 280 bp deletion with 88 bp insertion (containing inverted repeats) at V-J6 junction	V-J6 3' splice site mutated; mutations, deletions following J6	A 400 bp deletion preceding S μ	A large deletion from S γ to C _H 1 leaves its 3' end	Normal
α_1 -Yao	Normal	A 350 bp deletion at V-J5 junction	A 330 bp deletion with 62 bp insertion in the J5-J6 intron just 5' to J6	A short 10 bp deletion	A large deletion from S α to C _H 1 leaves its 3' end	Normal
α_1 -Mal	Complete deletion of the VDJ exon and its 5' and 3' flanks accompanied by a 360 bp insertion and followed with mutations and two short insertions			A 70 bp deletion with a 509 bp insertion and another 1.1 kb deletion preceding S μ	A large deletion from S μ to the C _H 1-C _H 2 intron	Normal
α_1 -Sec	A 17 bp deletion 5' to V (V 5' splice site altered)	A 330 bp deletion with 289 bp insertion (containing a direct repeat) at V-J5 junction	NS	1.3 kb deletion with a 57 bp insertion (containing a direct repeat) preceding S μ	A large deletion from switch to the C _H 1-C _H 2 intron	A 369 bp deletion 3' to C _H 3 involving the secreted form α poly (A) site

NS, not sequenced.

region, making this case actually belong to the following group.

- Most proteins contain an amino-terminal V region fragment of variable length followed by an internal deletion. Some such proteins also contain a sequence corresponding to part of J_H and hence have two deletions.
- A few proteins have an amino-terminal sequence with no homology with any known human sequence.

Most HCD proteins have a high carbohydrate content, with unusual moieties containing galactosamine.

Cellular and nucleic acid data

HCD proteins are synthesized as truncated HCs, without important postsynthetic degradation, although limited proteolysis is observed in a few cases, leading to heterogeneous amino termini in some. mRNA are short. Southern blotting shows clonal rearrangements of the relevant HC gene. The abnormalities of the productive gene are simple in the case of μ -HCD BW; alterations of splice sites of the VDJ exon by a deletion-insertion and mutations force a direct splice from the leader exon to C_H1. The other studied genes bear complex, different but similar abnormalities (Table 1). The VDJ exon is

Figure 1 Structure of HCD proteins. Except when stated (*in vitro* for Omm in whom the native protein is known from biosynthesis experiments, and 'intracellular?' for protein sequences deduced from mRNA sequences), the structures shown are those of the serum proteins.

entirely or most often partly (leaving the 5' end of V and the 3' end of J_H) deleted, and its 3' flank bears insertions and deletions. Part of the switch region is removed by one or two deletions, one of which encompasses C_{H1} (entirely or partially). These abnormalities lead to various mRNA splicing patterns removing the possible residual 3' end of C_{H1}. Entire free HCs are not secreted. They are retained and degraded in the endoplasmic reticulum due to an interaction with chaperone proteins such as the immunoglobulin binding protein BiP which occurs through the CH1 domain of the HC. As most HCD proteins lack CH1, they escape the interaction with BiP. As for those rare cases of μ -HCD with a deletion of the V domain only, normal LCs are produced which are noncovalently associated with the HC intracellularly, preventing interaction with BiP. Insertion of DNA of unknown origin is constant, usually at the location of deletions. In three genes such insertions include an exon. The unknown sequences present in the mature transcripts are absent from the serum protein in the two cases studied, probably due to amino-terminal proteolysis. In the nonsecretory α -HCD SEC, a further genomic deletion removes the polyadenylation signal of secreted α chains, forcing plasma cells to produce membrane α chains only.

Although LC – mostly κ – gene rearrangement seems to be constant, there is usually no detectable LC synthesis in γ - and α -HCD. In the single such γ -

HCD case studied, a productive rearranged κ gene bore numerous mutations in the VJ region, some of which altered both splice sites of the VJ exon, with direct splicing from the leader exon to C κ . A deletion and two insertions were found in the 3' flank of VJ. These LC abnormalities are reminiscent of those of the HC genes.

HELICOBACTER PYLORI, INFECTION AND IMMUNITY

Diane G Newell, Central Veterinary Laboratory, New Haw, Addlestone, UK

Characteristics of the organism and its antigens

Helicobacter pylori is a gram-negative, S-shaped, motile, microaerophilic bacterium which is characterized by the production of significant quantities of urease and the presence of multiple (5–7), unipolar, sheathed flagella with terminal bulbs. *H. pylori* primarily colonizes the gastric epithelium of humans and some nonhuman primates. Infection is probably acquired in childhood and colonization, once established, is probably lifelong. This infection is almost always associated with histologic chronic (type B) gastritis and is a major risk factor for the develop-

ment of peptic ulceration, atrophic gastritis, gastric cancer and gastric lymphoma.

H. pylori isolates are biochemically and antigenically surprisingly homogeneous despite significant genomic variation. Recently the entire genome of one *H. pylori* strain has been sequenced. A number of antigens of *H. pylori* have now been identified, including the urease which is a 540 kDa multimeric, immunodominant protein comprising six subunits of two polypeptides (28 kDa and 61 kDa) encoded by the *ureA* and *ureB* genes respectively. Monoclonal antibodies directed against the 28 kDa polypeptide can inhibit the enzyme's activity. This urease is antigenically highly conserved among a wide variety of other spiral gastric colonizing organisms, indicating

that the enzyme has evolved with an essential role in gastric epithelial colonization. A third polypeptide (54 kDa), frequently associated with the urease, is an hsp60 homolog (GroEL-like) encoded by the HspB gene.

The flagella of *H. pylori* comprise two immunogenic flagellins (about 54 and 56 kDa) encoded by the *flaA* and *flaB* genes. The flagella sheath material is antigenic and at least some of its antigens are distinct from the outer membrane of the bacterium. Flagella-associated proteins are antigenically cross-reactive with the flagellins of the campylobacters.

About 60% of *H. pylori* strains express an 87 kDa antigen which is the polypeptide subunit of the 970 kDa multimeric VacA protein possessing vacuolating cytotoxic activity. The subunits are encoded by the *vacA* gene which is also present in nontoxigenic strains. There is also a cytotoxin-associated protein (120–140 kDa) expressed from the *cagA* gene and present in about 80% of strains. The CagA protein is not required for toxin activity but may have a role in its regulation. Both the CagA and VacA proteins are highly antigenic.

H. pylori produces a variety of hemagglutinins, including the *N*-acetylneuraminyl-lactose-binding fibrillar-like hemagglutinin encoded by the *HpaA* gene, but their role in specific adherence to gastric epithelial cells is still debatable.

Immune responses of the host

H. pylori colonization of the gastric mucosa induces detectable circulating and local humoral responses. The isotypes of the antibodies produced are consistent with a prolonged chronic mucosal infection. Circulating immunoglobulin G1 (IgG1) and IgG4, and frequently IgG2, antibodies are observed but IgG3 and IgM antibodies are rare. IgA antibodies are also usually observed. In a well-documented volunteer study, IgG seroconversion occurred between 22 and 33 days after infection. Subsequent studies showed an initial IgM response, followed much later by an IgA seroconversion. At the local mucosal level, IgA antibodies predominate and are secreted into the gastric juice. IgG and IgM antibodies are also produced locally, although IgG reactivity is rapidly lost in gastric juice. The systemic IgG response persists throughout infection and only falls slowly after successful treatment, attaining basal levels after 12 months or so. Recurrence of infection is accompanied by a rapid rise in titer.

The specificity of the circulating host antibody response to *H. pylori* is complex and extremely variable, which seems to be a reflection of differences in the immune responses rather than the antigenic

diversity of the bacterium, other than for variation in the VacA and CagA proteins. It seems likely that the epithelial cell damage, the massive infiltration of immunocompetent cells, the efficiency of the antigen-presenting cells and the chronic nature of the infection all contribute to this variation. Most infected individuals produce antibodies against a large number of antigens, including the urease subunits, the flagellins and the 54 kDa hsp60 homolog. When present in the infecting strain, there are usually circulating antibodies directed against the VacA and CagA polypeptides. The specificity of the host mucosal response is also complex but may differ from that of the systemic antibodies even when of the same isotype.

ELISA-based serological tests are used routinely for detection of infection in patients with dyspepsia and for seroepidemiological surveys. The antigens used vary in complexity but all include the urease. Most recently tests for salivary IgG antibodies have been introduced which are noninvasive and particularly useful in children. In general, tests to monitor the success of treatment have not been useful because of the persistence of the circulating antibodies.

H. pylori-associated gastritis comprises an infiltration of plasma cells, lymphocytes and monocytes into the superficial layers of the lamina propria, sometimes causing a loss of gastric mucosal architecture. This gastritis is usually active, involving a polymorphonuclear infiltrate adjacent to areas of bacterial colonization.

Immunohistology indicates that approximately half the lymphoid cells are mature B cells, with the production of primarily IgA, but also IgG and IgM antibodies. Evidence suggests that these cells secrete immunoglobulin directed against *H. pylori*. The T cells present are mostly of the CD8⁺ subset; however, there is a significant increase in CD4⁺ T cells in *H. pylori*-positive gastritis. There is also an increase in $\gamma\delta$ T cells, which may not be specific for *H. pylori* infection. During infection there is an aberrant expression of HLA-DR antigens on the gastric epithelial cells and a local production of lysozyme and lactoferrin. Additionally, *H. pylori* infection is associated with an increased production of interleukin 1 (IL-1), IL-6 and tumor necrosis factor α (TNF α) in the gastric mucosa. In particular *H. pylori* has been shown to induce the expression of IL-8 in gastric epithelium, which would stimulate neutrophil chemotaxis. This stimulation may be related to the cytotoxin/CagA phenotype of the strain. Many of these responses are related to the severity of disease. Evidence suggests that these cellular responses initiate long-term immunopathological events as a consequence of the infection. Such events could play

a key role in the pathogenesis of the diseases associated with *H. pylori* infection, including ulcerogenesis and atrophic gastritis leading to gastric cancer.

Non-Hodgkin lymphoma affecting the stomach (MALT lymphoma) is associated with *H. pylori* infection in about 92% of cases. A causative role for *H. pylori* in this disease is supported by evidence that *H. pylori* colonization can also induce the formation of lymphatic aggregates and lymphoid follicles in the gastric mucosa, and that antimicrobial therapy leading to eradication of the infection results in regression of disease.

Evasive strategies by the organism

H. pylori colonization persists in an apparent immunologically hostile microenvironment; however, no evidence for bactericidal activity of the local antibodies can be demonstrated. The gastric epithelium is not an immunoprivileged site. Immunoglobulin coating of bacteria, except those deep within the gastric pits, occurs *in situ* but these antibodies do not appear to be bactericidal. Bacterial mechanisms of immune avoidance may include a continuous loss of highly antigenic material, including the urease and flagella sheath, from the bacterial surface, thereby reducing the effectiveness of bound antibodies. Downregulation of the immune response during infection may also occur as antigen-specific responsiveness of local and circulating T cells is significantly reduced in *H. pylori*-positive compared with *H. pylori*-negative individuals, suggesting that these cells have been tolerized.

Vaccines

The ineffectiveness of the host immune response dur-

ing infection and frequent reinfection, or recrudescence of infection, in treated patients indicates that protective immune responses will be difficult to develop. Nevertheless, current results indicate that oral subunit vaccines, comprising bacterial sonicates, the UreB polypeptide (but not the UreA or jack bean urease) or the GroES and GroEL homologs, particularly when used with a mucosal adjuvant such as cholera toxin, can protect in animal models such as *H. felis* infection in mice. Interestingly, it also appears that oral immunization can eradicate a pre-existing experimental infection, suggesting that immune therapy may be an option. However, these animal models may not reflect human protective immune responses against *H. pylori* and more complex vaccines may be required. Moreover, the effects of vaccination on the immunopathological events associated with *H. pylori* infection need to be carefully considered before such an approach is adopted.

HELPER T LYMPHOCYTES

Frank W Fitch, Division of Biological Sciences, The Ben May Institute, The University of Chicago, Chicago, USA

It was not until the late 1950s that lymphocytes were shown conclusively to be the essential specific cell of the acquired immune response. James Gowans showed that depletion of lymphocytes by chronic drainage of thoracic duct lymph, which contained only lymphocytes, abolished immune responses; the resulting immune deficiency could be restored completely by administration of thoracic duct lymphocytes. Within a few years Jacques Miller and others were able to define two separate lineages, initially on

the basis of function: T lymphocytes, which developed and matured in the thymus from precursor cells that originated first in the yolk sac and later in the bone marrow, carried out the functions of cell-mediated immunity; B lymphocytes, which were derived from cells that had their origin in the bursa of Fabricius in birds and the bone marrow in mammals, produced antibody. Although B lymphocytes were the cells which produced antibodies, it was quickly recognized that stimulation of B cells

not all T cell clones fit into these two categories, and additional subsets secreting other arrays of cytokines have been described. However, T cell clones secreting simultaneously the cytokines which have been attributed uniquely to T_H1 and T_H2 cells often are unstable. These clones may represent cells isolated before the process of differentiation has been completed.

In addition to having different functions, the various T cell subsets respond differently to several regulatory processes. Some of the factors that favor the selective growth of murine T_H1 or T_H2 clones have been defined. The patterns of immune responses observed in different situations suggest that the preferential growth and differentiation of one or another T cell subset can account for unusual features of some diseases. For example, infection with *Leishmania major* causes a progressive fatal disease in BALB/c mice, while limited disease and cure of infection are observed in C57BL/6 mice; the immune manifestations observed in these two mouse strains correspond to a predominantly T_H2 response to BALB/c mice and a predominantly T_H1 response in

C57BL/6 mice. The preferential involvement of subsets, mediated by particular immunoregulatory events, may also operate in autoimmune diseases.

HEMATOPOIETIC STEM CELL TRANSPLANTATION

Peter A McSweeney and **Rainer Storb**, University of Washington School of Medicine and Clinical Research Division, Fred Hutchinson Cancer Research Center, Seattle, Washington, USA
Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The last 10 years have seen a rapidly increasing use of hematopoietic stem cell transplantation as treatment for a variety of malignant and nonmalignant diseases. This has come about due to improvements in supportive clinical care which have reduced the morbidity and mortality of the procedure. In addition, discoveries in basic research have led to developments of new pharmaceutical and recombinant materials which are redefining the practice of stem cell transplantation. This entry will review the basic principles of stem cell transplantation, results of treatment, newer developments and likely future directions.

Background

Initially, most transplants were performed for younger patients with leukemia or aplastic anemia

and involved the use of marrow donors who were human leukocyte antigen (HLA)-identical siblings. Because of initial success and improving outcomes, the use of allogeneic stem cell transplantation has broadened to include a variety of severe hematologic diseases, including genetically-based diseases of the hematopoietic and immune systems (Table 1). Improvements in prevention of graft-versus-host disease (GVHD) have allowed the use of partially HLA-mismatched family donors, and increasingly, unrelated donors. An even greater increase has taken place in the use of autologous stem cell transplantation for hematologic malignancy and solid tumors, particularly as a treatment for breast cancer.

The conceptual basis for stem cell transplantation for malignancy is that it allows delivery for supralethal doses of chemotherapy and radiation in an attempt to overcome tumor resistance. In treatment

Table 1 Diseases currently treated with stem cell transplantation

Malignant	Nonmalignant
Acute leukemias (AML/ALL)	Aplastic anemia

Neuroblastoma	
Various sarcomas ^a	
Germ cell tumor ^a	

^aAutologous transplants almost invariably used.

of nonmalignant diseases such as aplastic anemia the goal is to replace a defective hematopoietic or immune system, and less intensive therapy may be sufficient to facilitate engraftment of donor cells. In both situations, long-term hematopoietic and immune functions are reconstituted from so-called stem cells transferred with the graft. These cells home to the marrow environment and give rise to long-term multilineage hematopoiesis.

Source of hematopoietic stem cells

Historically, most transplants were performed using marrow 'harvested' from the donor pelvis. Recently, there has been increasing use of hematopoietic stem cells collected from the blood by leukapheresis, and the term stem cell transplant now appears to be more appropriate than bone marrow transplant. Large numbers of hematopoietic progenitors circulate in the blood after treatment with chemotherapy and/or recombinant growth factors, such as granulocyte colony-stimulating factor (G-CSF) or granulocyte-macrophage colony-stimulating factor (GM-CSF), and transplantation of these cells, primarily to date for autografting, is associated with rapid hematopoietic recovery. Preliminary data using peripheral blood progenitors for allografting also indicate an engraftment benefit, but there may prove to be an increased risk of chronic GVHD due to the high doses of T cells given.

Donors used are usually HLA-identical siblings. Approximately 25% of patients have such a donor, and in some cases phenotypically HLA-matched or HLA-nonidentical family donors can be used. Rarely an identical twin is available, and from an immunologic standpoint these donors are ideal. Increasingly used are phenotypically HLA-matched unrelated

donors identified through national or international donor registries.

Autologous transplant requires the cryopreservation and storage of the patient's own stem cells. Since these transplants are almost always performed for malignancy, the graft may be treated *in vitro* in an attempt to remove residual tumor cells, e.g. with monoclonal antibodies or chemotherapeutic agents.

Conditioning regimens

The most frequently employed regimen used before allografting for the treatment of malignancy has been a combination of cyclophosphamide (CY) and total body irradiation (TBI). An antitumor dose-response relationship has been found for TBI as demonstrated by lower relapse rates in patients receiving high (15.75 Gy) as opposed to lower (12 Gy) doses of TBI (Figure 1A). Because of greater toxicity, there has been no survival gain from using the higher doses of radiation (Figure 1B). Fractionation of TBI reduces radiation-induced side-effects without significant loss of antileukemic activity. Attempts to increase the antileukemic efficacy of the regimens has involved

Figure 1 Outcome after allogeneic transplantation using HLA-matched sibling donors for AML in first remission illustrating effects of radiation dose on (A) relapse and (B) overall survival. Patients were treated in Seattle at the Fred Hutchinson Cancer Research Center and randomized to receive cyclophosphamide 120 mg kg⁻¹ and either TBI 12 Gy (2 Gy $\times$ 6) or TBI 15.75 Gy (2.25 Gy $\times$ 7). Seattle data as of 1996.

Thiotepa
Bischlorethyl nitrosurea (BCNU)
Carboplatin

replacing CY with other agents used in conjunction with TBI, or the use of regimens based on chemotherapy alone (Table 2). For autologous transplants where host immunosuppression is not required, multidrug regimens are often used. Despite a wide array of possible conditioning regimens that have been tested, no significant advances on the basic TBI-based regimens have been demonstrated to date.

Recombinant cytokines

Many cytokines have been identified that act on hematopoietic and immune cells (Table 3). Potential useful effects include stimulating hematopoietic progenitor proliferation, 'mobilization' of progenitors into the blood for collection, and stimulation of an immune recovery and antitumor activity. Cytokines currently in clinical use include G-CSF, GM-CSF, erythropoietin, interferon α and interleukin 2 (IL-2).

Table 3 Recombinant cytokines with a potential clinical role in stem cell transplantation

Hematopoietic growth factors ^a	Immunomodulatory factors ^a
GM-CSF ^b	Interferon α^b
G-CSF ^b	Interleukin 2 ^b
Erythropoietin ^b	M-CSF
Interleukin 1	Interferon γ
Interleukin 3	Interleukin 4
Interleukin 6	Interleukin 7
Interleukin 8	Interleukin 10
Interleukin 11	Interleukin 12
Stem cell factor	
Thrombopoietin	
FLT3/FLK2 ligand	
Leukemia inhibitory factor	
Oncostatin	

GM-CSF, granulocyte-macrophage colony-stimulating factor; G-CSF, granulocyte colony-stimulating factor; M-CSF, macrophage colony-stimulating factor.

^aMany of these factors are pleiotropic with effects on both hematopoietic and immune cells.

^bAvailable for clinical use.

Results of clinical stem cell transplantation

The vast majority of allogeneic stem cell transplants and almost all autologous stem cell transplants are undertaken for treatment of malignancy. The following section discusses the use of HLA-matched family donor transplants and autologous transplants. The choice of which type of transplant to perform is guided by a variety of factors, including disease type, patient age, likelihood of obtaining a useful autologous stem cell graft free of tumor, and physician preference.

Transplants for hematologic malignancy (Table 4)

Allogeneic stem cell transplantation is the only dem-

Table 4 Comparison of outcomes after allogeneic stem cell transplantation and conventional chemotherapy as treatment for hematological malignancies^a

Malignancy	Transplant		Chemotherapy ^b
	Relapse-free survival (%)	Relapse-free survival (%)	Relapse-free survival (%)

AML, acute myeloid leukemia; ALL, acute lymphoblastic leukemia; CML, chronic myeloid leukemia; CLL, chronic lymphocytic leukemia; HD, Hodgkin's disease; NHL, non-Hodgkin's lymphoma; CR, complete remission.

^aNote that some variation in outcomes has been reported, both with transplantation and with conventional therapy, that may not be reflected in these comparisons.

^bPatients failing conventional chemotherapy almost always die as a result of malignancy.

^cSimilar disease-free survivals have been shown with autologous bone marrow transplantation, but relapse rates are higher.

onstrated curative therapy for diseases such as chronic myeloid leukemia (CML) and myelodysplastic syndromes in which the stem cell compartment of the marrow is abnormal. In CML, excellent results have been achieved for patients transplanted in chronic phase using conditioning regimens of TBI/CY or busulfan (BU)/CY. Results are best if transplants are performed early after diagnosis and within the chronic phase (Figure 2) with relapse-free 5-year survivals of 60–70%. For patients with myelodysplastic syndromes, approximately 40% of patients are cured, with the best results seen in patients with less advanced myelodysplasia, where survivals are approximately 60%.

For patients with acute myeloid leukemia (AML) in first remission, approximately 50% of patients are cured and 25% relapse (Figures 1 and 3). For patients in first relapse or second remission, 3-year disease-free survival is approximately 34% (Figure 3). Patients with advanced refractory AML have a cure rate of 10–15%. Similar results have also been seen after allografting for the same disease stages in acute lymphoblastic leukemia (ALL). Patients with

Figure 2 Survival after allogeneic transplantation from HLA-matched siblings for CML. Patients received regimens containing CY/TBI or BU/CY. (A) Survival according to phase of disease at transplant. (B) Survival after transplant for chronic-phase patients according to interval from diagnosis to transplant. Patients received CY 120 mg kg⁻¹ and TBI 12 Gy or BU 16 mg kg⁻¹ and CY 120 mg kg⁻¹. GVHD prophylaxis was a combination of short methotrexate (days 1, 3, 6 and 11) and cyclosporine. Seattle data as of 1996.

Figure 3 Survival after allogeneic transplantation for AML according to disease stage at diagnosis. Seattle data as of 1996.

ALL are not transplanted in first remission unless adverse prognostic features for relapse are present. The outcomes of allogeneic transplant and autologous transplants have been similar for acute leukemia in remission. However, there is more transplant-related mortality after allografting and a higher relapse rate after autografting.

Transplants have now been widely used in the treatment of non-Hodgkin's lymphoma, Hodgkin's disease and multiple myeloma and, to a lesser extent, chronic lymphocytic leukemia (CLL), almost always after failure of conventional therapy. As seen in acute leukemia, relapses are more frequent after autografting but toxicity is greater after allografting. Results of allografting and autografting are similar for lymphoma except for low-grade lymphomas, where allografting appears to have better curative potential. Allografting can cure patients of CLL and possibly multiple myeloma. Many autologous transplants have been performed for myeloma but cure using this approach has not been demonstrated.

Transplants for solid tumors

The use of high-dose chemotherapy followed by autologous transplantation has been tested in a variety of solid tumors. When patients have metastatic disease, results are poor. Best responses are seen in diseases that are often responsive to conventional dose chemotherapy, e.g. breast cancer. Because of the poor results in patients with metastatic disease, high-dose therapies are now being tested as adjuvant therapy for patients with chemosensitive solid tumors at high-risk of relapse, e.g. with breast or ovarian cancer. Preliminary results of autografting in patients with high-risk stage II and III breast cancer indicate that relapses are delayed, and possibly prevented with 3-year relapse-free survivals of 70% reported after transplant, as compared with 40–50%

for patients receiving conventional adjuvant chemotherapy.

Transplants for nonmalignant disorders

Stem cell transplantation for nonmalignant disorders has almost exclusively involved the use of allogeneic transplants from HLA-identical siblings. Initially, most experience involved transplants for aplastic anemia where stem cell transplantation could cure 50% of patients, but graft rejection and GVHD were significant problems. Improvements in conditioning regimens and GVHD prevention have led to impressive survival rates of 85–90% in allograft recipients (Figure 4). Equally impressive, if still somewhat con-

Figure 4 Survival after allogeneic transplantation from HLA-matched siblings for aplastic anemia. (A) Improved survivals of patients treated in the last decade were a result of improved conditioning regimens and GVHD prophylaxis. The addition of antithymocyte globulin to cyclophosphamide-based conditioning regimens has largely eliminated graft rejection as a problem (1988–1995). (B) Effect of GVHD prophylaxis on survival showing results of a randomized study comparing prophylaxis with MTX/CSP (methotrexate/cyclosporine) versus MTX alone. Previous studies had shown that MTX and CSP were equivalent as single agents. Patients received CY-only conditioning regimens. Seattle data as of 1996.

troversial, has been the use of allografting for treatment of β -thalassemia. Results of transplants, primarily performed by the Pesaro group, have shown a cure rate of more than 90% for patients transplanted early in the disease course (Figure 5). Preliminary data indicate that similar results may be possible in sickle-cell disease. Transplants for genetically-based immune deficiency syndromes can cure diseases such as severe combined immunodeficiency disease.

Figure 5 Survival after allogeneic transplant at Pesaro for β -thalassemia using HLA-identical sibling donors. (A) Probability of survival, event-free survival and graft rejection in all patients. (B) Event-free survival according to disease stage based on extent of liver damage (due to iron overload from multiple transfusions and ineffective erythropoiesis). Early stage (class 1) patients have >90% rejection-free survival. Patients received conditioning regimens containing BU/CY and GVHD prophylaxis with MTX/CSP. Class 1, no hepatomegaly, no portal fibrosis; class 2, hepatomegaly or portal fibrosis; class 3, + hepatomegaly, + portal fibrosis. (Reprinted by permission of Blackwell Science, Inc. from Lucarelli G (1994) Bone Marrow Transplantation in Thalassemia In: Forman SJ, Blume KG and Thomas ED (eds) *Bone Marrow Transplantation*, 833–835, Blackwell Scientific Publications, Boston, USA.)

HLA-nonidentical stem cell marrow grafts

To extend the available donor pool and thereby offer potentially life-saving treatment, studies using HLA-nonidentical family members and phenotypically HLA-matched unrelated donors have been performed. A high incidence of acute and chronic GVHD and increased risk of graft rejection have been observed. The use of one-HLA-antigen mismatched donors and HLA-matched unrelated donors have been associated with acceptable results. In patients with chronic phase CML, who underwent unrelated donor marrow transplantation in Seattle, an impressive 70% 3-year disease-free survival has been achieved.

Complications of transplant

Factors influencing outcomes of transplant include age, type of transplant, disease type and stage, and pre-existing medical problems. The principal complications that adversely affect outcome include toxicity of conditioning regimens, immunologic deficiency, poor graft function, GVHD and relapse of disease.

Regimen-related toxicities

To achieve maximum antitumor effects, regimens have been intensified such that significant nonhematopoietic toxicities are seen (Table 5). The main life-threatening toxicities are veno-occlusive disease (VOD) of the liver and interstitial pneumonitis. Serious VOD is seen in 15–28% of patients, and severe idiopathic pneumonia in approximately 3% of patients. Long-term side-effects include endocrine dysfunction, infertility, cataracts and, in chil-

dren, impaired growth, impaired sexual function and reduced intellectual function. Late secondary malignancy is also a significant problem. Unique to autologous transplant recipients is the development of myelodysplastic syndromes, occurring in up to 20% of patients. The only cure for this life-threatening side-effect is a second transplant.

Hematologic and immune recovery

Recovery of granulocytes and platelets is usually complete by 40–50 days after transplant. Recovery of natural killer (NK) cells, monocytes and macrophages occurs early. However, functional defects, including defective immune function and chemotaxis, may persist for many months. Lymphocyte dysfunction is often prolonged and characterized by diminished humoral and cell-mediated response to antigen. Peripheral blood B cell numbers and function are depressed, and the T cells show depressed CD4 counts, increased CD8 suppressor activity and inverted CD4:CD8 ratios. Immune reconstitution is often complete by 1 year, but in patients with chronic GVHD sustained clinical and laboratory evidence of immune deficiency persists.

Infectious complications

Early in the post-transplant period there is severe neutropenia of 2–3 weeks duration and, although bacterial infection is common, the availability of potent antibiotics means that death from bacterial sepsis is uncommon. More difficult problems are viral and fungal infections and, in particular, cytomegalovirus (CMV) infections. Reactivation of CMV from host or transfused cells in the early post-transplant months can cause life-threatening pneumonia, previously fatal in approximately 15% of those receiving allografts for malignancy. Effective preventative measures have included use of CMV-seronegative blood products in CMV-seronegative transplant recipients, and more recently prophylaxis with ganciclovir. Fungal infections due to candida or aspergillosis are increasingly seen and are often resistant to drug therapy. Herpes simplex is seen commonly after transplant and is prevented with acyclovir. Varicella zoster reactivation occurs in about 40% of cases and is treated effectively with acyclovir. *Pneumocystis carinii* infection, which previously caused about 10% of post-transplant pneumonias, is prevented with prophylactic trimethoprim-sulfamethoxazole.

Graft-versus-host disease

Acute GVHD is caused by alloreactive T cells directed at non-MHC (major histocompatibility

complex) antigens recognized on host antigen-presenting cells, or against MHC antigens when MHC disparity exists. A complex series of cellular interactions that generates a cascade of cytokine release appears to be important in pathogenesis. Target organs for inflammation are the skin, liver and gastrointestinal tract. Principal risk factors for GVHD are summarized in Table 6. Between 20 and 50% of patients receiving HLA-identical sibling-donor transplants develop significant acute GVHD, and this is associated with significantly increased risk of transplant-related mortality, primarily as a result of infectious complications due to immune suppression.

Attempts to prevent GVHD are necessary and usually involve administration of immunosuppressive agents (Table 7), most commonly cyclosporine, methotrexate and corticosteroids. Indefinite im-

munosuppression is not required and transplant tolerance usually develops by 3–6 months. The combination of cyclosporine and methotrexate is better GVHD prophylaxis than either agent alone and leads to improved survival in patients with less advanced malignancy and nonmalignant disorders (Figure 4).

With aggressive malignancy, improved GVHD control may be associated with relapse rates, suggesting a loss of graft-derived antitumor effect. Newer, promising agents include FK506 and mycophenolate mofetil. A highly effective alternative approach to GVHD prevention involves removing T cells from the graft. However, this results in greater risks of graft rejection and relapse, with no survival gain. Treatment of established GVHD primarily involves the use of corticosteroids, antithymocyte globulin (ATG), cyclosporine and, increasingly, other agents listed in Table 7.

Chronic GVHD, defined as GVHD occurring after 100 days post transplant, clinically resembles autoimmune diseases such as scleroderma, Sjögren's syndrome and primary biliary cirrhosis. Severe immune deficiency persists and infection is the most frequent cause of death. Chronic GVHD of some degree occurs in 30–50% of patients receiving HLA-matched sibling transplants, usually within 2 years of transplant, and is associated with reduced probability of survival. The most effective therapy involves use of prednisone plus or minus cyclosporine. Other drugs with an increasing role include FK506 and thalidomide.

A relationship between relapse rates and previous GVHD has been established. Development of clinically significant acute or chronic GVHD provides some protection against relapse (graft-versus-leukemia effect), and for patients with advanced leukemia may lead to improved overall survival. In practice, it has not been possible to control GVHD with any precision to exploit this benefit during the transplant process. However, it has been possible to treat some cases of relapsed leukemia, most notably patients with CML, with infusions of donor buffy coat cells and induce second complete remissions, including possible cure.

Graft failure

Poor graft function is common after transplant but often resolves after contributing factors such as infection and drugs are dealt with. Persistent poor graft function is associated with a high mortality and the use of recombinant hematopoietic growth factors improves survival. True immunologic graft rejection is uncommon after the use of TBI-based conditioning regimens, except when HLA-mismatched donors are used and/or the graft is T cell depleted. The addition

HEMOLYTIC DISEASE OF THE NEWBORN

Cyril A Clarke, formerly at Department of Genetics and Microbiology, University of Liverpool, Liverpool, UK

For this article, hemolytic disease of the newborn (HDN) is taken to be the condition resulting from blood group incompatibility between mother and fetus, and clinically 'rhesus' (Rh) disease is the most important example.

During pregnancy, and particularly during the trauma of delivery, some fetal red cells may cross the placenta and enter the maternal circulation. When the mother is Rh negative and the fetus Rh positive (paternally derived), the fetal cells may immunize the mother, and when this happens the important antibody which she produces is of the immunoglobulin G (IgG) (7S) class. This can cross the placenta and coat, thereby damaging the fetus's Rh positive red cells, causing anemia, jaundice and edema.

Immunization can now usually be prevented by injecting the mother after delivery with anti-Rh (D) gammaglobulin. This eliminates any fetal Rh-positive cells which have entered the mother's circulation and therefore protects the next Rh-positive baby. The first one in any case usually escapes, since the maternal IgG antibody is slow to form.

In 1938, Ruth Darrow, an American doctor who herself had had a succession of affected babies, was the first to suggest that an incompatibility was the cause, but she attributed this to differences between fetal and adult hemoglobin rather than between blood groups.

In 1939, Levine and Stetson described a group O woman who needed a transfusion after a delivery. Though she was given her husband's group O blood, she nevertheless developed a severe transfusion reaction and it was found that her serum agglutinated her husband's cells, suggesting the presence of a new antibody.

For some years, Landsteiner and Wiener had shown that rabbits injected with the blood of rhesus

monkeys formed antibodies which not only agglutinated the monkey's red cells but also those carrying the human M antigen. However, in 1940, they discovered that when the anti-M had been absorbed, the rabbit serum still agglutinated most human bloods independently of their MN types. The new blood group system was therefore designated Rh.

In 1941, Levine and colleagues put the Rh blood groups firmly on the map with regard to pregnancy, for they noted that transfusion accidents tended to be associated with pregnancy, the explanation being that the mother had previously been immunized by an Rh-positive fetus. They also discovered that it was necessary to test for Rh antibodies at body (not room) temperature, and this is why these antibodies had not been detected earlier.

It was obvious, therefore, that the first step in preventing RhHDN was to ensure that all Rh-negative women needing transfusion were given Rh-negative blood.

Naturally occurring protective mechanisms

Although 1 in 7 of all matings in the UK are between Rh-negative women and Rh-positive men, Rh immunization is much less frequent than expected for the following reasons:

1. The husband may be heterozygous.
2. Transplacental hemorrhage may never take place.
3. The mother may be a 'nonresponder' (about 30% of Rh-negative individuals do not make antibodies when injected with a small volume of Rh-positive cells).
4. The fetus may be incompatible with the mother on the ABO system. For example, in a group O

mother with a group A or B fetus, the mother's naturally occurring anti-A or anti-B (mostly IgM) will eliminate any fetal cells before they have time to stimulate the production of Rh antibodies.

Blocking (incomplete) antibodies

Sometimes the Rh antibody cannot be detected, even at body temperature, in mothers who have had RhHDN babies. This is because the antibody, though present, is 'hidden'. When Rh-positive cells are suspended in the suspected serum, and anti-D (IgM) is added, the cells are not agglutinated (as would be expected). This is because the antigen sites have already been blocked with the mother's IgG blocking, or incomplete, anti-D. ('Blocking' is the term used by Wiener – it is synonymous with 'incomplete', as used by Race.)

The antiglobulin test (Coombs' test)

When blocking antibody is present, the antiglobulin test, which is a test for any antibody on red cells, gives positive results.

The baby's red cells are washed and an equal volume of rabbit antihuman globulin (AHG) is then added. If there is IgG (i.e. blocking anti-Rh) on the red cells, the AHG will cause agglutination (this is the direct Coombs' (antiglobulin) test).

The antiglobulin test should be carried out regularly on the cord blood whenever HDN is a possibility.

Rh nomenclature

In the Fisher-Race nomenclature, an individual inherits a set of three Rh genes from each parent and the loci are all on chromosome 1. They are responsible for D or d, C or c, E or e, and the genotyping of an individual is carried out by testing his or her red cells against anti-D, anti-E, etc. (anti-d has never been found). D is clinically the most important of these antigens and there is a rare weak form called D^u. As the tests for detecting D^u become more sensitive, an individual's Rh blood group may very occasionally appear to change from Rh negative to Rh positive.

Clinical features

Hemolytic anemia is the result of the maternal antibody having coated the red cells of the baby, resulting in their removal to the spleen. Generalized bleeding, jaundice, edema, and sometimes damage to

the central nervous system occur. Hydrops (Figure 1), the result of low plasma protein, anemia and heart failure, is now increasingly rare because of modern therapy.

Serological aspects of HDN

The Rh D antigen is the most potent, and c next; then (outside the Rh system) the Kell antigen. Anti-Kell is usually the result of a blood transfusion, most people being Kell negative and therefore incompatible pregnancies rare. In theory, any IgG anti-blood group antibody present in the mother can cross the placenta and cause HDN.

Figure 1 Hydropic baby, the result of rhesus hemolytic disease. Anemia is often another feature.

Prediction of severity

There is a correlation between maternal anti-D concentration and the severity of HDN. Furthermore, there are subclasses of anti-D which are associated with different degrees of severity. The antibody-dependent cytotoxicity test (ADCC), using monocytes and lymphocytes, is also useful. Liley spectral absorption curves, whereby the severity of the disease is judged by the bilirubin content of the amniotic fluid, are now somewhat out of date. For the newborn baby, the best single criterion of severity is cord hemoglobin – normal 13.6–19.6 g dl⁻¹, moderately affected around 12.8 g dl⁻¹.

Treatment of the established disease

Transfusion with Rh-negative blood is the keynote. Exchange transfusion after birth is still used, because free maternal Rh antibody continues to act for several days after birth.

Before birth, intraperitoneal transfusion (blood is absorbed through the lymphatic vessels of the fetus) arrests the deterioration of the fetus and gains a few weeks gestation. More recently, direct intravascular fetal blood transfusion of Rh-negative blood, using ultrasound to guide the needle into the umbilical vein, is used. The quantity of blood to be transfused and the volume to be exchanged is calculated with the goal of achieving a hematocrit of 30–40%.

Plasmapheresis is popular but the beneficial effects are not proven. Phototherapy is of much more use in the jaundice associated with prematurity than in that due to Rh.

Prophylaxis

Fetal cells in the maternal circulation can be easily recognized using the Kleihauer technique (Figure 2), and the size of any transplacental hemorrhage thereby assessed. Anti-D gammaglobulin should be given to all non-immunized Rh-negative women after delivery of an Rh-positive baby, and it should be injected into the deltoid muscle of the mother within 48 h of delivery. The anti-D coats the D antigen sites on the fetal cells and prevents immunization. The standard dose is 500 iu but more may be needed, depending on the Kleihauer count. For an abortion up to 20 weeks 250 iu is the standard. Occasional failures of prophylaxis occur but if antenatal anti-D is given at 28 and 35 weeks as well as post delivery, the failure rate is very small. However, antenatal anti-D as a routine is wasteful (though monoclonal anti-D will eventually make supplies easier). An economical compromise is to restrict the antenatal

Figure 2 Fetal cells in the maternal circulation demonstrated by the Kleihauer technique. The adult hemoglobin in the mother's red cells is eluted by an acid phosphate buffer and they appear as 'ghosts', whereas the fetal hemoglobin is not eluted and the cells therefore stand out and can be readily counted.

regimen to primigravidae because with this a woman is highly likely to have at least two babies free of RhHDN.

A comparative aspect in monkeys

Interestingly in some species, the Rh mechanism is present but no disease results. Thus IgG antibodies are formed by the monkey mother, cross the placenta, and give a positive antiglobulin test on the fetal red cells, yet the offspring are never jaundiced. The probable reason is that the antibody concentration is not high enough to cause hemolysis.

ABO Hemolytic disease

ABO incompatibility has already been mentioned (see Naturally occurring protective mechanisms) and ABO hemolytic disease might be expected to be very common, but the anti-A and anti-B are mostly IgM and therefore do not cross the placenta. Mild cases are fairly frequent, but in some parts of the world there are areas where it is both much more common and more severe, e.g. Jamaica. Here ABO antibodies may arise from antigens derived from food and from the bacterial flora in the gut, and in Jamaica the antibody titers may be as high as 2000–4000. Interestingly, the infant may have overt evidence of hemolysis in the absence of a positive antiglobulin test, the converse of what often happens in RhHDN. The reason is not known, but the explanation may lie in differences between the Rh and ABO antigens.

The treatment of ABO HDN is on the same lines as for RhHDN – exchange transfusion is carried out

using group O red cells taken from a donor with very low anti-A or -B titers.

HEPATITIS A VIRUS, INFECTION AND IMMUNITY

Ian D Gust, CSL Ltd, Parkville, Victoria, Australia

Hepatitis A is an acute, self-limiting infection of the liver, caused by an enterically transmitted picornavirus. As the virus is not cytolytic, liver cell damage is assumed to be immunologically mediated. While frequently asymptomatic, especially in the young, infection occasionally results in fulminant hepatitis and death. Recovery from the disease is accompanied by lifelong protection against reinfection. Protection is mediated by circulating antibodies and can be passively transferred.

Hepatitis A has a relatively short incubation period (15–49 days), is transmitted fecal orally and is followed by long-lasting immunity that can be passively transferred. In 1973, virus-like particles were identified in the feces of volunteers experimentally infected with the MS-1 strain of hepatitis A virus (HAV). These particles were specifically aggregated by convalescent, but not by preinfection, serum. The identification of the etiological agent – and the demonstration that infection could be trans-

mitted to marmosets – ushered in a new era of research leading to the development and licensing of a safe and effective vaccine.

Virology

Classification

Hepatitis A virus is a member of the Picornaviridae family and the sole member of the genus *Hepatitis A virus*. There are four recognized genotypes, but only one serotype.

HAV is spherical, nonenveloped and measures 27–28 nm diameter; it is more resistant to heat than other picornaviruses, remaining stable after incubation at 56°C for 30 min, several weeks at room temperature and years at –20°C, although it can be inactivated by heat (121°C for 30 min) or exposure to hypochlorite (1.5–2.5 mg l⁻¹ for 15 min). The virus is known to infect humans, juvenile chimpanzees and several *Saguinus* species of marmosets.

Epidemiology

Prevalence of infection

Although hepatitis A has a worldwide distribution, there are wide differences in its incidence. Under conditions of overcrowding, especially when there is limited access to clean water and inadequate disposal of human feces, HAV infection is common and occurs early in life. These infections are usually clinically inapparent. By contrast, where high standards of hygiene and sanitation apply, most children reach adult life without encountering the virus.

Epidemiologic patterns

Two patterns of age-specific prevalence of anti-HAV are commonly recognized: 1) Pattern A is typical in countries with poor standards of hygiene and sanitation: most children are infected by the age of 5 years and the prevalence of anti-HAV is virtually 100% by the age of 10 years. This pattern may also be seen in disadvantaged groups in affluent countries. 2) Pattern B is typical of most developed countries. The sigmoidal curve reflects a steady decline in the rate of infection over many years. Paradoxically, as living standards improve, the incidence of hepatitis A may rise, as most of the infections which occur are delayed until adult life, when they are more frequently associated with jaundice.

Hepatitis A has become a significant problem among travelers, as large numbers of people from low prevalence countries take holidays in regions with high rates of infection. Hepatitis A is now the most common vaccine-preventable disease of travelers, the risk of acquiring the disease being 100 times greater than typhoid fever and 1000 times greater than cholera.

Clinical features

Clinical course

The mean incubation period from infection to the onset of symptoms is 4 weeks. Patients with hepatitis A often describe a vague illness appearing between 1 and 7 days prior to the onset of dark urine.

The first objective sign of disease is the onset of dark urine, which is followed within a few days by pale or clay-colored feces and yellow discoloration of the sclera, skin and mucous membranes. The return of color to the stools, which usually occurs within 2 or 3 weeks after the onset of illness, is a good sign of resolution of the disease.

Laboratory diagnosis

Acute hepatitis A is not distinguishable from other forms of viral hepatitis on clinical grounds, although the diagnosis may be inferred in a patient with typical symptoms and the appropriate epidemiologic clues. Liver function tests, especially serum levels of alanine aminotransferase (ALT) and aspartate aminotransferase (AST), are sensitive measures of parenchymal liver damage, but are not specific for hepatitis A.

The diagnosis of acute hepatitis A is most commonly confirmed by detection of specific anti-HAV immunoglobulin M (IgM), using either ELISA or radioimmunoassay.

Prevention

General

Control of hepatitis A may require social, educational and engineering initiatives. Provision of clean water, proper disposal of feces and alleviation of crowded living conditions rapidly reduces the incidence of hepatitis A and other enteric infections.

Passive immunization

Until recently, the only means of preventing hepatitis A was administration of pooled human immunoglobulin (HNIG), which was first shown to be effective in large-scale studies among American soldiers during World War II. If administered prior to exposure, HNIG can reduce the incidence of hepatitis A by up to 90%.

Active immunization

Three parenterally administered hepatitis A vaccines have been developed and are currently licensed for use in humans. Each of these is produced from inactivated cell culture-derived virus and they obtain their effects by inducing circulating antibodies to antigens present on the surface of the virus.

Clinical trials indicate that inactivated hepatitis A vaccines are safe, highly immunogenic and provide excellent protection against infection. Several million doses of the vaccine have been administered without serious adverse events.

Therapy

As no specific therapy exists, management is largely supportive.

HEPATITIS B VIRUS, INFECTION AND IMMUNITY

Howard C Thomas and **Jennifer A Waters**, Department of Medicine, Imperial College of Medicine, St Mary's Hospital, London, UK

Hepatitis B virus (HBV) infection is a major public health problem, infecting approximately 300 million people worldwide, and is a major cause of chronic liver disease and hepatocellular carcinoma (HCC). The majority of adults infected have a transient hepatitis from which they completely recover and clear the virus. Rarely the disease becomes fulminant and the patient may die. Between 5 and 10% of adults become persistently infected and develop chronic liver disease. In the majority of cases of vertical transmission the virus is not eliminated and the child becomes chronically infected, greatly increasing its risk of developing cirrhosis and HCC.

Virology

HBV is a member of the Hepadnaviridae, a related group of hepatotropic, enveloped, double-stranded DNA viruses which have small genomes. The HBV genome is 3.2 kb in size and contains four open reading frames (Figure 1). These encode the envelope (hepatitis B surface antigen, HBsAg), nucleocapsid

(hepatitis B core and 'e' antigens, HBcAg and HBeAg), DNA polymerase and X protein.

The envelope of the virus contains the large, middle and major surface proteins, which all contain the same carboxyl terminus of 226 amino acids. The middle protein has an additional 55 amino acids designated the pre-S2 region, and the large protein has a further 120 amino acids designated the pre-S1 region. All of these proteins also occur in a glycosylated form.

The core gene encodes two overlapping polypeptides. The longer of these polypeptides contains a signal peptide which directs it to the endoplasmic reticulum where the amino- and carboxy-terminal ends are cleaved and HBeAg is secreted into the circulation. The smaller polypeptide has a nucleophilic sequence at its carboxy-terminal end and associates with the RNA pregenome of the virus during the initial stage of the formation of nucleocapsids. The X open reading frame encodes a protein which has the ability to modify the transcription of both viral and host cell genes.

Figure 1 The genetic organization of hepatitis B virus. The HBV virion contains a circular, partially double-stranded DNA genome which contains four overlapping open reading frames. Gene C encodes the two nucleocapsid antigens, HBcAg and HBeAg, gene S encodes the small, middle and large surface antigen proteins, region P the viral polymerase and region X the X protein.

The largest open reading frame encodes for a bifunctional protein which has DNA polymerase and reverse transcriptase functions. This enzyme is central to the replication of the virus. The first stage of viral replication is the synthesis of a positive strand RNA molecule by host cell RNA polymerase. This positive RNA molecule acts as a pregenomic template for the viral polymerase/reverse transcriptase, allowing transcription of a DNA copy which is then itself transcribed to give the double-stranded DNA genome of the virus.

At some stage of chronic HBV infection, viral sequences become integrated into the genome of the liver cells. There is a preferred site within the cohesive end region of the viral genome, at which integration occurs. The integration into the host genome appears to be random. In some cases, this integration event has resulted in the activation of a proto-oncogene and malignant transformation has followed. In other HCCs, the site of integration of the virus is distant from the position of the activated oncogene. The role of the X protein in transactivation of endogenous oncogenes remains to be determined. In the UK, less than 50% of HCCs contain episomal or integrated HBV sequences and it has been suggested that in the majority of cases the association of the virus with HCC occurs because of the ability of the

virus to induce cirrhosis rather than because of a direct relationship to the activation of oncogenes. Rarely, when HCC occurs in a noncirrhotic liver, insertional mutagenesis is probably involved in carcinoma formation.

Immunobiology

HBV is not thought to be directly cytopathic; the liver damage in both the acute and the chronic disease are probably caused by the host immune response.

Acute hepatitis B infection

High titers of immunoglobulin M (IgM) anti-HBc, thought to be predominantly a thymus-independent response, appears early in the course of acute HBV infection, together with HBsAg and HBeAg (Figure 2). Anti-pre-S1 may also occur early in the course of infection. This is accompanied by a vigorous major histocompatibility complex (MHC) class I restricted cytolytic T lymphocyte (CTL) response against multiple epitopes throughout the structural and non-structural proteins of the virus. The CTLs, by direct lysis of infected hepatocytes, are thought to be important in clearance of the virus. There is also some evidence for a role in viral elimination of the

Figure 2 The natural history of acute HBV infection. HBsAg and HBeAg can be detected early in the serum, prior to the onset of clinical hepatitis. Antibody to pre-S1 can sometimes be detected during this early phase. AST (aspartate aminotransferase) is an indication of lysis of infected hepatocytes.

cytokines interferon γ (IFN γ) and tumor necrosis factor α (TNF α).

There is a strong MHC class II restricted T helper cell proliferative response to the nucleocapsid antigens, HBcAg and HBeAg, but not to the envelope proteins, during the early phase of acute hepatitis B. The association of recovery with the presence of the MHC class II locus DRB1*1302 supports an important role for the CD4 response in recovery.

Elimination of the virus from the liver results in the loss of HBeAg from the serum and the detection of anti-HBe. Loss of HBsAg and the appearance of anti-HBs occurs a little later.

Persistent hepatitis B infection

In some patients HBV is not successfully eliminated by the immune response and the patients become chronically infected. It is likely that there are many different reasons why patients develop the chronic carrier state, and the liver pathology is probably the result of a dynamic equilibrium between the replication of the virus and the host's immune response.

Mechanisms of viral persistence

Chronic HBV infection following exposure in neonatal life The majority of babies born to HBeAg-positive mothers become infected and over 90% of these develop a chronic carrier state. Although some cases have been documented of HBV infection during fetal life, it is thought that these infants probably receive a large inoculum of virus from maternal blood before or during birth, and by close contact with secretions soon after birth. HBeAg but not HBsAg has been detected in the cord blood of these neonates, suggesting that HBeAg crosses the placenta. The reason for the infants failing to clear the virus is unknown, but may relate to the induction of

immune tolerance to HBeAg. Children born to HBeAg-negative/HBsAg-positive carrier mothers who are asymptomatic rarely become chronically infected.

Chronic HBV infection following exposure after the neonatal period In marked contrast to the situation at birth, in young African children, more than half of whom have been infected by 7 years of age, only 15% fail to clear the virus. The majority of adults who become infected have an acute disease and eliminate the virus; in 5–10% of these cases, however, HBV persists. Persistent infection in adults is associated with poor T cell proliferative and cytotoxic responses to HBV antigens, although there is no evidence of a general immune suppression. This antigen-specific state of tolerance may be the result of the genetic background of the host: the MHC class II allele DRB1*1302 which is associated with clearance of the virus is virtually absent in adults and children who have persistent infection.

Natural history of persistent HBV infection There are four phases of the chronic infection (Figure 3).

HBeAg-positive phase During this phase there is little immune-mediated lysis of infected hepatocytes. The CD4 response to HBcAg is minimal and there is no response to HBsAg. The CTL response is largely undetectable.

Figure 3 Natural history of persistent HBV infection after neonatal or adult exposure. During conversion from HBe antigenemia to the presence of anti-HBe, viremia ceases. The hepatitis associated with this seroconversion is the result of immune lysis of hepatocytes supporting HBV replication. This immune pressure may select an HBe-negative strain of HBV which causes viremia in the absence of HBeAg. AST, Aspartate aminotransferase (an indication of lysis of hepatocytes).

HBeAg/antibody seroconversion phase As the infection continues, the inflammatory liver disease becomes more active. Between 5 and 15% of persistently infected patients undergo spontaneous HBeAg/antibody seroconversion each year, as do approximately 40% of those treated with IFN α . This seroconversion event is usually accompanied by hepatocyte death, as indicated by raised liver enzymes. The mechanism by which seroconversion occurs is unknown. In the early stages of seroconversion an increased T cell proliferative response to the nucleocapsid antigens is seen, and is taken to indicate an increase in the numbers of nucleocapsid sensitized T cells. In addition, when serum transferases are at their highest a nucleocapsid antigen-specific MHC class I restricted CTL response can be demonstrated, although it is considerably lower than in acute disease.

Anti-HBe-positive patients with no evidence of HBV replication This phase follows the HBeAg/antibody seroconversion hepatitis which results in clearance of hepatocytes supporting HBV replication. The sera of these patients do not contain virus particles detectable by dot-blot hybridization. However, in some cases, low levels of viremia can be detected by the polymerase chain reaction. HBsAg in these patients is encoded by integrated HBV DNA sequences. This phase represents immune control of the virus.

Anti-HBe-positive patients with persistent HBV replication These patients are infected with a mutated HBV which is unable to encode HBeAg. The most common mutation is a G to A change at nucleotide 1896, creating a novel translational stop codon in the pre-core region of the genome. Chronic infection with this mutant virus may be associated with a severe and progressive liver disease and is more prevalent in Mediterranean and Far Eastern patients.

This mutation is found as a very minor species in some patients with an HBeAg-positive infection. The mutant is selected at the time of seroconversion to anti-HBe in some patients. These patients usually become HBV DNA negative by hybridization initially and chronic infection develops only after a long interval, presumably because the mutant virus escapes from immune control. The mutant virus can be shown to have a statistically higher rate of amino acid substitution in regions of the virus encoding known B cell epitopes, which may also contain CD4 T cell epitopes, presumably representing the emergence of variants that can replicate in the presence of these components of the immune response. The mutant virus is thought not to be more cytopathic

than the wild-type virus and the pathology is probably immune mediated.

Vaccines

HBsAg, derived from infected serum or produced by recombinant DNA technology, has been shown to induce protective immunity against HBV infection. These vaccines are now in widespread use throughout the world. When used to prevent neonatal transmission from infected mothers, the best protection is achieved when given with hyperimmune globulin.

Although the majority of patients vaccinated with HBsAg are protected from further infection, 2.5–5% of immunocompetent adults do not respond, probably for genetic reasons. This percentage is greater in some high-risk groups of patients, such as hemodialysis patients, in which the failure rate is approximately 40%; this probably represents a secondary immune deficiency due to the renal disease.

There has been considerable debate on whether the middle pre-S2-bearing and large pre-S1-bearing polypeptides should be added to existing vaccines. Experiments in mice suggested that both the pre-S1 and -S2 regions can recruit T cell help independently for the production of anti-HBsAg. It has also been suggested that pre-S1 is the region of the virus which binds to the hepatocyte during infection: antibodies to this region might be virus neutralizing and, therefore, inclusion of the pre-S1 region in a vaccine may be desirable.

The antibodies to HBsAg in convalescent serum (>80%) bind predominantly to the common 'a' determinant epitopes found in the hydrophilic region of the polypeptide between amino acids 124 and 147. The carboxy-terminal region of HBsAg has 14 cysteine residues and the antigenicity of this protein is highly dependent on its conformational structure. Using two cyclical peptides analogs of amino acids 124–137 and 139–147 and a panel of monoclonal antibodies binding to these regions, it has been possible to show in chimpanzees that antibody to the region aa124–137 of HBsAg prevents infection. Antibodies to this region, as well as to other epitopes on the surface antigen gene encoded polypeptide, are present in the serum of patients convalescent from HBV infection and in normal subjects immunized with plasma-derived and recombinant DNA-produced vaccine.

Genetic variation of HBsAg

Patients with chronic liver disease and no serum markers of current HBV infection except for HBV DNA have been described. The first indication that this

may be due to a mutation in the surface gene of the virus was described in a child born to an HBsAg-positive mother who became HBsAg positive despite passive and active immunization at birth and the development of high titer anti-HBsAg. A point mutation in the gene which resulted in an amino acid substitution from glycine to arginine at amino acid 145 of HBsAg was observed. This change was later shown to alter the common 'a' determinant so that it was not recognized by the known protective anti-HBsAg response.

This particular mutation has been found in a number of vaccine recipients around the world and in one patient not known to have been immunized. This virus was also shown to be transmissible in chimpanzees, and in mice the variant HBsAg, although eliciting a high titer antibody to the variant, produced only a low titer of antibody recognizing the native protein.

Other variants of HBV which have amino acid changes in the common 'a' determinant have now been described in patients and vaccinees with chronic liver disease. The effect of these mutations on the

immunogenicity and antigenicity of the HBsAg remains to be formally evaluated.

HEPATITIS C VIRUS, INFECTION AND IMMUNITY

William L Irving, Department of Microbiology, University of Nottingham, Nottingham, UK

Hepatitis C virus (HCV) was first characterized in 1989, following successful cloning from copy DNA extracted from infectious chimpanzee plasma. The natural route of infection is unknown, but HCV is blood borne, and therefore high-risk groups for infection include intravenous drug users and recipients of unscreened blood and blood products (e.g. hemophiliacs). Sexual transmission does not appear to be a major route of spread of infection. Vertical transmission from carrier mothers is around 2–10%. Estimates of the prevalence of infection vary between 0.1 and 1% of the population of Europe and the USA. There may be significant fluctuations from this in other countries – for example, rates of 15–20% anti-HCV positivity have been reported in Egypt. The majority (possibly 75%) of HCV infections result in chronic carriage of the virus. The percentage of chronic carriers who will progress to clinically significant liver disease (chronic hepatitis, cirrhosis, hepatocellular carcinoma) is unknown, but a conservative estimate is 20%. HCV infection is also

associated with autoimmune phenomena such as the anti-LKM-1 reactivity of autoimmune hepatitis type 2, and the development of mixed essential cryoglobulinemia type II. Viral and host factors which determine the variability in clinical outcome are poorly understood. Current therapy (interferon α , IFN α) is expensive, prolonged (6–12 months) and has a 'cure' rate of only 20%. More encouraging results have been reported in small-scale trials of combination therapy comprising IFN α plus ribavirin.

Characteristics of the organism and its antigens

HCV is an enveloped virus containing a single-stranded positive-sense RNA genome of 9.4–9.5 kb. It is classified as a separate genus within the family Flaviviridae. The genome includes a 5' nontranslated (noncoding) region (5'NCR) of 329–341 nucleotides, followed by a large single open reading frame

encoding a polyprotein precursor of 3010 amino acids (AA) in length, and a 3' NCR. The open reading frame is translated as a polyprotein containing (from N to C terminus) the core protein (p22), two envelope glycoproteins E1 (gp35) and E2 (gp70), and a series of nonstructural proteins (NS2-5) (Figure 1). The E2 gene contains a hypervariable region encoding a domain of 27 amino acids in length. The NS gene products are essential for virus replication, and possess a number of enzymatic properties: protease (NS2, NS3), helicase (NS3), and RNA-dependent RNA polymerase (NS5).

There is considerable sequence variability between isolates, which are classified into six (at present) major genotypes on the basis of 5'NCR and NS5 gene sequence analysis, each of which contains a number of subtypes. The most conserved part of the genome is the 5'NCR (>90%), followed by the core gene (>80%), the least conserved being the 3'NCR (26%), and the E1 and NS2 genes (55–60%). Genotype distribution around the world is uneven: types 1, 2 and 3 predominate in Europe and the USA, 4 is found in the Middle East, 5 in southern Africa and 6 in China. Studies of potential differences in pathogenicity between the genotypes have been inconclusive. All known genotypes may give rise to life-threatening liver disease. Genotype 1 viruses are less sensitive to IFN α therapy than are the other genotypes.

Diagnostic antibody tests utilize a series of recombinant or synthetic peptide antigens. First generation assays contained only an NS4-derived antigen, c100. These assays were of low sensitivity and specificity. Second generation tests added core (c22) and NS3 (c33) gene products to the c100, resulting in considerable improvement in diagnostic accuracy. Current, third-generation, assays also include an NS5 gene product. Commercially available screening assays are in standard sandwich ELISA format. Confirmatory assays, essential in the context of screening of low-risk sera, such as from blood donors, rely on the same antigens, but in immunoblot or 'line assay' format, where the antigens are presented on nitro-

cellulose strips. The presence of the relatively conserved core and NS3 gene products are essential to avoid false-negative reactivity arising through failure of antibodies raised against one viral genotype to recognize antigens derived from a different genotype. In contrast, the genetic diversity of the NS4 gene is reflected in sufficient antigenic differences between genotypes to allow synthesis of type-specific NS4-derived peptides for use in serotyping assays. Genome detection assays, such as the reverse transcriptase polymerase chain reaction (RT-PCR) using primers from the highly conserved 5'NCR, are useful for determination of carrier status in anti-HCV-positive individuals. Genotyping of the infecting virus may be determined by use of type-specific primers, by restriction fragment length polymorphism analysis of PCR products, or by hybridization of PCR products with type-specific probes.

Immune responses of the host

The sensitivity of the current serological assays is such that specific antibody responses are detectable in the vast majority of HCV-infected individuals. The only exceptions to this are patients who are immunosuppressed at the time of infection, where RT-PCR positivity may be the only indication of infection, and in the weeks following acute infection, as it may take up to 6 months for anti-HCV reactivity to develop. The clinical and biological significance of antibodies to HCV-derived polypeptides present in diagnostic assays is still unknown. They are clearly not protective, as the majority of anti-HCV positive sera are also RT-PCR positive. It is possible that antibodies against the envelope glycoproteins may have neutralizing activity, but assays for the detection of anti-E1 and -E2 are not widely available, and neutralization studies are severely hampered by the lack of a routine cell culture system for HCV.

Cellular immune responses to a variety of recombinant viral antigens have been studied in proliferation and cytotoxicity assays. CD4⁺ T cell proliferative responses to both structural (core, E1) and non-

Figure 1 The hepatitis C virus genome. c22, c33 and c100 refer to the location of antigens used in diagnostic assays for the detection of anti-HCV.

structural (NS3, NS4) HCV-derived proteins have been identified in cells from both peripheral blood and liver tissue of anti-HCV positive individuals. Which (if any) of these responses correlate with clearance of virus, or at least with lack of progression of liver disease, is unclear. Preliminary data suggest that chronic progressive liver disease may be associated with T_H2 patterns of cytokine production from liver-derived T cells. HCV-specific cytotoxic CD8⁺ T lymphocytes (CTL) have also been identified in HCV-infected individuals, but again, variable results have been reported. Some groups suggest that these cells may be compartmentalized within liver tissue, but others have no apparent difficulty in finding such cells within peripheral blood. Lack of standardization of experimental assays may underlie these discrepancies. Target epitopes within both structural and nonstructural proteins have been mapped.

Evasive strategies by the organism

The majority of HCV-infected individuals become chronic carriers of the virus, even though they possess easily demonstrable, broad-ranging humoral and cellular immune responses. A number of hypotheses have been advanced to explain the failure of these responses to eliminate virus.

Both low- and high-density HCV virions may be found in human sera, the multiple densities reflecting association of virus with various lipoproteins and/or antibody. The ability of HCV to associate with very low-density lipoproteins, thereby rendering a major proportion of infectious virus nonneutralizable, may be of importance for virus persistence.

The existence of HCV as a quasispecies (i.e. a population of viruses each with slightly different sequences) may allow the virus to escape immune surveillance by changing its antigenic determinants. The hypervariable region of E2 shows considerably less genetic divergence in chronically infected patients who are agammaglobulinemic, as compared with immunocompetent hosts, while persistence of infection in chimpanzees has been associated with the emergence of cytotoxic T lymphocyte (CTL) escape mutants, with critical amino acid substitutions within T cell epitopes. Both of these lines of evidence support the concept that host immune responses, whether humoral or cellular, drive the evolution of variant viruses with an enhanced ability to persist in the host.

The existence of extrahepatic sites of replication

of HCV may be another mechanism of immune evasion. Most studies have relied on detection of negative-strand RNA, a replicative intermediate, as evidence of HCV replication. Strand-specific amplification assays are, however, technically fraught, and this topic remains controversial. Nevertheless, extrahepatic sites may exist, and may be important for virus persistence – for example, if replication within cells of the immune system is able to interfere with the host immune response, or if the site in question is inaccessible to the immune system.

Vaccines

Vaccine development is at a preliminary stage. Obstacles to be overcome include the diversity of HCV genotypes and subtypes and the hypervariability of HCV quasispecies within an individual host. An understanding of protective mechanisms of immunity would also greatly facilitate vaccine design. Experimental recombinant envelope glycoprotein vaccines induce anti-E2 responses in chimpanzees, associated with protection against low dose challenge with homologous virus. However, the duration and cross-reactivity of this protection appears to be very limited. Broadly-reactive CTL responses have been induced in mice using peptide-based vaccines derived from the core and NS5 genes.

HEPATITIS E, F AND G VIRUSES, INFECTION AND IMMUNITY

Michael A Purdy, Hepatitis Branch, Division of Viral and Rickettsial Diseases, National Center for Infectious Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia, USA

In the 1970s the development of sensitive and specific serologic assays for markers of acute infection by hepatitis A virus (HAV) and hepatitis B virus (HBV) showed that enterically and parenterally transmitted viral hepatitis, not caused by HAV or HBV, occurred throughout the world. Two of these viruses, HCV and HEV, have been isolated, cloned and sequenced. In the 1980s the development of serologic assays for these viruses indicated that additional enterically and parenterally transmitted hepatitis-associated viruses exist. Research is ongoing to elucidate the immunology, clinical features and pathology associated with these viruses.

Hepatitis E virus

Hepatitis E virus (HEV) is a member of the Caliciviridae family. Hepatitis E (HE) is a self-limiting disease, similar to hepatitis A, with no known tendency for chronicity. Hepatitis E occurs as large scale epidemics in developing countries, and also as sporadic cases. Outbreaks have been reported and confirmed either serologically or with the reverse transcriptase polymerase chain reaction (RT-PCR) in over 30 countries throughout the world.

The primary source of infection is usually drinking water contaminated with water from a sewage system. Person-to-person contact has been noted as a very rare cause of transmission, and in a recent outbreak in India vertical transmission of HEV from infected mothers to infants during the third trimester of pregnancy was noted. Initial reports of HE epidemics failed to find cases of HE in pediatric populations; however, the development of diagnostic tests have shown HEV is a common cause of acute hepatitis in this age group. The attack rate is highest in young to middle-aged adults between 15 and 40 years of age. While the seroprevalence of anti-HAV may approach 70–90% in young children in endemic areas, seroprevalence of anti-HEV is less than 10% in young children and approaches 40% in middle-aged adults. In most reported outbreaks there is no significant difference in the attack rate of HE between genders in the general population (1–15%), but attack rates for pregnant women are significantly higher (17–40%), with case fatality rates approach-

ing 20%. The case fatality rate for the general population in endemic regions is about 0.5–4%.

Localization of HEV epitopes

HEV genomic RNA is composed of three open reading frames (ORFs) that code for the various proteins involved in the replication of nascent virions. The deduced amino acid sequence for the three ORFs has been used to synthesize overlapping peptides for enzyme immunoassays to detect potential epitopes in these ORFs. Although potential epitopes have been located in all three ORFs, epitopes near the carboxyl termini of the deduced ORF2 and 3 amino acid sequences have proven to be most useful in the development of immunoassays and prototype recombinant vaccines.

Clinical features

Typically the incubation period for HE is about 6 weeks, with a range of 2–9 weeks. Clinical HE occurs in two phases. First, the prodromal phase is usually characterized by fever and nausea. Second, the icteric phase, which lasts about 2 weeks, is characterized by jaundice and dark urine. General symptoms include abdominal pain, anorexia, hepatomegaly, splenomegaly and vomiting. Fulminant hepatic failure, particularly among pregnant women in the second and third trimester, has been associated with HE, although it is not a regular sequela of this disease. Diagnostic testing has shown that subclinical infection occurs in pediatric and adult populations.

The patterns of viremia and virus excretion are not well characterized in humans and only limited data exist from experimental animal models (cynomolgus macaques). In humans, viremia has been detected by RT-PCR within 2 weeks after the onset of illness and persists for 4–16 weeks in some individuals. Virus excretion has been detected by immunoelectron microscopy (IEM) in feces, predominantly in the first week following the onset of acute icteric hepatitis, and may persist for 2 weeks, with one report documenting excretion for up to 52 days. In macaques RT-PCR has been used to detect viremia within 4 days after experimental infection, which persists for up to 2 weeks after the onset of illness. Virus excretion in experimentally infected macaques has

been detected as early as 2 weeks before the onset of illness and may persist for up to 2 weeks after the onset of acute illness.

Pathology

Morphologic features of HE in liver tissue specimens include those of cholestatic and standard (noncholestatic) types of acute viral hepatitis. In cholestatic HE, bile stasis is observed in canaliculi and gland-like transformation is seen in parenchymal cells. Less frequently seen changes in liver cells include acidophilic bodies and focal necrosis. Portal ducts are enlarged with inflammatory infiltrate that may spill over into neighboring parenchyma. Infiltrates consist of lymphocytes, polymorphonuclear leukocytes and macrophages. In standard HE, ballooned hepatocytes, acidophilic degeneration of hepatocytes and acidophilic body formation are frequently seen. Focal intralobular necrosis of hepatocytes, with accumulations of lymphocytes, mononuclear macrophages and activated Kupffer cells, is also an important morphologic feature. In an IEM examination of liver biopsies taken from three patients, Dienes and colleagues found the predominant subpopulation of lymphocytes in the infiltrate were CD8⁺ T cells (51%), 16% were CD4⁺ T cells, 19% displayed Leu-7 (CD57) antigen, and 14% were positive for B1 (CD20). HLA-DR was found on all Kupffer cells, and HLA class 1 antigens were expressed on hepatocytes.

Antibody response in infected individuals

In humans an immunoglobulin M (IgM) response is mounted against HEV during the acute phase of the disease. The peak titer of HEV-specific IgM usually coincides with the peak of serum alanine aminotransferase activity and generally falls off to undetectable levels about 5 months after the immune response is initiated. HEV-specific IgG titers peak during the early convalescent phase of an HEV infection and decline over the next several months. Although HEV-specific IgG falls to undetectable levels in over 50% of postinfection individuals, studies have shown IgG is detectable in some individuals from 2 to about 14 years after infection. The presence of pre-existing HEV-specific IgG appears to prevent reinfection and clinical HE in young adults. In a study of HE patients in Somalia HEV-specific IgA titers appeared to rise and fall in conjunction with IgM titers, but the prevalence of specific IgA (52%) in these patients was lower than that of IgM (73%).

Prophylaxis

When travelers were passively immunized with

immune globulin prepared from plasma collected in nonendemic countries they were not protected from infection when they traveled to endemic regions. Studies using immune globulin prepared from donors in India, an HEV-endemic country, showed no difference in attack rates for HEV infection among passively immunized and nonimmunized individuals during an HE outbreak. However, passive immunization of macaques with convalescent phase plasma from a macaque previously infected with HEV prevented clinical disease when the immunized macaques were challenged with HEV, but failed to prevent viral replication or shedding. Active immunization of macaques with recombinant vaccine also led to prevention of clinical illness, but also failed to prevent viral replication or shedding.

Hepatitis F viruses

Serologic testing has identified five hepatropic viruses; HAV, HBV, HCV, HDV and HEV. These viruses account for almost all human viral hepatitis; however, a small percentage of patients exhibiting the signs and symptoms of acute viral hepatitis do not have serologic evidence of infection with any of these viruses. Researchers continue to search for the viruses associated with non-ABCDE hepatitis. Many of these enterically and parenterally transmitted viruses have been tentatively designated hepatitis F virus (HFV). However, at this time no single virus has been recognized as being HFV. Some researchers have suggested the non-ABCDE viruses are really one of the known hepatitis viruses and serologic testing has failed to detect the viral-specific antibodies present in infected individuals. Serologic testing of individuals with HCV and HEV infection has shown that the serologic tests available for these viruses do not detect every infected individual. It has also been suggested that a new serotype of HBV may be responsible for some so-called non-ABCDE hepatitis.

Hepatitis G virus

Recently, a new hepatitis-associated virus, hepatitis G virus (HGV), has been cloned and sequenced. HGV, an RNA virus, is a member of the Flaviviridae family, and is distantly related to HCV. Originally this virus was one of the viruses referred to as HFV. Although HGV has been identified as a hepatitis-associated virus and is associated with acute and chronic hepatitis, research has failed to prove that HGV is hepatotropic. At this time no serologic test exists for detection of HGV-infected individuals, as no HGV antibodies have been detected in infected individuals using either recombinant HGV proteins

or synthetic peptides. The only way to detect HGV is with RT-PCR.

HERPES SIMPLEX VIRUS, INFECTION AND IMMUNITY

Barbara A Blacklaws, Department of Clinical Veterinary Medicine, University of Cambridge, Cambridge, UK

Anthony A Nash, Department of Veterinary Pathology, University of Edinburgh, Edinburgh, UK

Infection by herpes simplex virus (HSV)

There are two related subtypes of herpes simplex virus: types 1 (HSV-1) and 2 (HSV-2), now called human herpesviruses 1 and 2 respectively. Both are large, double-stranded DNA viruses (ca. 150 kb)

encoding 70 or more proteins (HSV-1 has now been completely sequenced). The virion has a large icosahedral nucleocapsid core containing the viral genome as a linear double-stranded DNA molecule. This is surrounded by an amorphous protein-filled tegument which is then enclosed in

a membrane envelope containing virion glycoproteins.

Infection starts with attachment of the virion to the cell surface. At present, a number of viral glycoproteins and cellular receptors have been implicated: glycoprotein B binds heparan sulfate on the cell surface whilst glycoprotein C binds complement receptor 1 (CR1 or CD35). Also involved are glycoproteins D and H as well as the cell's basic fibroblast growth factor receptor. Once attached, the virion envelope must fuse with the cytoplasmic membrane to release the viral core into the cell. The core is then transported to the nuclear pores where the viral genome is released into the nucleus to undergo replication and expression. Expression of viral genes may be divided into three broad categories: α (immediate early), β (early) and γ (late) genes with transcription and translation taking place in the nucleus and cytoplasm respectively. The progeny virion core is assembled in the nucleus and is thought to then bud out through the nuclear membrane to be transported to the endoplasmic reticulum and Golgi apparatus of the cell where it reacquires its envelope as it buds out from the plasma membrane.

This would be the normal lytic virus lifecycle seen in epithelial cells, however HSV can establish latent infections of neurons in the sensory nervous system. The actual mechanism for establishing, maintaining and reactivating latency is not understood although productive replication is not necessary for establishment. During a latent infection the viral genome is maintained as a multicopy circular episome in the nucleus. There is a family of spliced RNAs present called the latency-associated transcripts (LATs). These transcripts are not required for the establishment or maintenance of latency. Virus reactivates from neurons through an unknown stimulus although *in vitro* the presence of nerve growth factor stops reactivation.

HSV-1 is associated primarily with orolabial infections, whilst HSV-2 is usually associated with genital lesions; however, these sites are not mutually exclusive. Both viruses are transmitted by direct contact from a productively infected to an uninfected individual through skin abrasions or at mucosal surfaces. Vesicular skin lesions or shallow ulcers on mucosal surfaces result due to the lytic infection of epithelial cells by the virus. Large quantities of virus appear between the epidermal and dermal layer in fluid containing cell debris, inflammatory cells and giant cells. Progeny from this surface infection may pass into sensory nerve endings of the dermis and be transported up the nerve axon by retrograde transport to the cell body as a naked nucleocapsid. An acute infection of the peripheral nervous system may result

and usually a latent infection is established primarily in the sensory ganglia (see **Figure 1A**) but latently infected neurons have also been recovered from the central nervous system. There have been reports of latently infected tissues outside the nervous system but these have been difficult to confirm.

Latent infections in sensory ganglia are reactivated periodically by unknown means (emotional and physical stress, exposure to UV light, hormones and tissue damage have all been implicated) to produce viral progeny which are transported back down axons to the skin at or close to the original site of infection. Here the virus re-establishes a productive lytic infection which may result in asymptomatic virus shedding or a recurrent (recrudescent) lesion as is suffered by many in the population (**Figure 1B**). HSV-1 reactivates preferentially from cervical and trigeminal ganglia whilst HSV-2 reactivates more readily from sacral ganglia. Recurrences are more likely to occur after severe primary infections and their frequency decreases with time. Reactivated infections may well not reseed the original neuron, which survives infection as sensation is not lost from the periphery even after multiple reactivations.

The first problem for the host in defending itself against HSV is the site of infection. The skin and nervous system have been called 'immune privileged' sites and certainly the immune surveillance occurring in these tissues is not as great as in highly vascularized tissues such as the liver. To compound this problem, especially in recrudescent lesions, the virus is restricted to the epidermal layer until a well-established infection results in enough cell death to cause inflammation in the dermal layer. The second problem for the host is that once the virus has established a latent infection, no detectable viral products are expressed and so there is apparently no way for the host's immune system to attack latently infected cells. However, the immune system does have an important part to play in restricting the severity of HSV infection. Primary infections are usually confined to the skin and dorsal root ganglia but in unusual circumstances a disseminated systemic infection with brain damage and fatal consequences may result. This is seen in patients with T cell defects and neonates. Immunosuppression also increases the risk of recurrences whilst in normal hosts secondary infections are of shorter duration than primary infections.

Immune responses of the host

The immune response to HSV has mainly been studied in animal models of infection (e.g. mice, rabbits and guinea pigs). Although various routes of

Figure 1 Map of HSV infection and immune responses. (A) Acute infection: 1, HSV productively infects cells of the epithelium; 2, viral progeny transfer to neural dendrites which they infect; 3, naked viral capsids are transported up the neuron axon to the cell body; 4, productive infection may occur or latency may be established in the nucleus. (B) Reactivation: 5, a latent infection is reactivated to produce progeny in the cell body; 6, progeny are transported down the nerve axon; 7, virions infect epithelial cells to cause a productive lytic infection; 8, virus may be transferred to an uninfected individual.

infection are used that are not always consistent with the natural route of infection in humans, some understanding of the host's response to these viruses has been achieved (Table 1).

The host animal has a natural genetic resistance to infection with HSV which may involve several mechanisms including macrophage and natural killer (NK) cell activity or interferon production. Many experiments in this field used unnatural routes of infection but it would seem that good NK cell activity and interferon production are important if the HSV infection occurs through mucosal surfaces

(Figure 1A). These responses would act immediately to restrict an infection but are not themselves sufficient to clear the virus; rather, it is the specific immune response of the host which will eventually remove an acute infection. Both antibody and T lymphocytes are induced a few days after a primary infection is established. These would be too late in preventing infection of neural tissue from this primary infection but they do restrict the peripheral and neural infection and eventually clear the virus.

Important target antigens for antibody are virion and infected cell glycoproteins, capsid proteins and

Table 1 Site of action of immune effectors

Site of infection	Immune effectors

Epithelium	+++	-	-	++
Epithelium to nervous system	-	-	+	-
Nervous system	-	++	-	-

some infected cell polypeptides. In normal naive mice, passively transferred antibodies to HSV will protect from lethal doses of HSV (mice would normally die from encephalitis) but antibody alone is not sufficient to clear virus from the periphery or the nervous system. Consequently it may have a role in retarding the spread of virus to and through the nervous system. However, to be effective it must be present in high titers within 24–48 h of infection and may act at several sites by restricting the area of epidermal infection, the number of progeny produced from this infection or interfering with the passage of virus from the epidermis to and through the nervous system (Figure 1). Several *in vitro* activities of HSV-specific antibody may be measured (e.g. virus neutralization, antibody-dependent cellular cytotoxicity and complement-mediated cytotoxicity) but the important activity *in vivo* is in dispute. However, it may prove to be the target antigen's function and/or concentration in the virion or infected cell which will determine the protective ability of an antibody. In humans, reactivation and recurrence or reinfection with HSV is often in the face of high neutralizing serum antibody levels, suggesting that antibody is not protective.

T lymphocytes are extremely important during HSV infections: T cell-depleted or nude mice die from encephalitis after HSV infection but are protected by the transfer of immune T cells. However, there are several T cell subsets involved and the role of each is gradually being clarified.

The cytotoxic T lymphocyte (CTL) response to HSV can be seen after lymphocytes are cultured *in vitro*. The response after stimulation with live virus antigen is major histocompatibility complex (MHC) class I-restricted and mediated by CD8⁺ T lymphocytes in both mice and humans. Glycoproteins have been the major protein group studied in mice with reports of recognition of glycoproteins B, C and D, although the MHC background of the host may affect the response. Nonstructural proteins of the virus also act as target antigens; the immediate early proteins of HSV account for up to 50% of the CTL response in some mouse strains. Humans have high CTL precursor levels in the blood probably because of constant stimulation by the virus and CTL clones derived from an HSV-2-infected individual were either HSV-2 specific or cross-reactive with HSV-1 and recognized immediate early and virion proteins and glycoprotein D-2.

The actual role of the MHC class I-restricted response during an HSV infection is best shown by the *in vivo* depletion of CD8⁺ T cells in mice. There is no effect on the clearance of a peripheral viral infection but there is a more florid ganglionic infec-

tion (Figure 1A). When high doses of virus are inoculated, depleted mice tend to die from the infection. This leads to the theory that CD8⁺ T cells may be involved in a reduction of the acute nervous system infection. CTLs do not kill neurons which lack expression of MHC class I however, and may act through cytokine release after recognition of a non-productive infection in capsular (microglial) cells. During immunopathological responses (e.g. herpes keratoconjunctivitis) CD8⁺ T lymphocytes may be involved in suppressing anti-HSV responses as depletion of CD8⁺ cells aggravates the condition.

The other major T cell subset, CD4⁺ (MHC class II-restricted) lymphocytes, is involved in several functions including the delayed-type hypersensitivity (DTH) response to HSV, CTL activity and T cell help (e.g. in antibody production). The predominant cells to infiltrate a cutaneous lesion are activated macrophages and CD4⁺ T cells, suggesting a role for both in virus clearance. Studies using gene knockout mice have shown that CD4⁺ cells are essential for virus clearance and it is the T_H1 subset which appears to be protective (Figure 1). It is likely that CD4⁺ cells mediate antiviral immunity directly by lysing MHC class II-bearing infected cells or through the release and activity of cytokines such as interferon γ (IFN γ) or tumor necrosis factor. Nitric oxide production may also play a role in virus clearance. Glycoproteins, virion (VP16) and immediate early (ICP27) proteins all induce CD4⁺ T cells but glycoprotein D has proven to be the most protective HSV protein studied to date in mice. $\gamma\delta$ TCR⁺HSV-specific T cell clones have also been isolated from humans, although their function is unknown.

Most experiments in mice use acute primary infections, but in the guinea pig vaginal model, recurrent infections may be studied. Here there is apparently an impaired cell-mediated response (decreased cytokine production and the presence of suppressor cells) to HSV in animals which suffer recurrent infections. The above dysfunctions in immune function have also been implicated in allowing recurrent infections in humans.

Evasive strategies by the organism

HSV has several mechanisms for evading the host immune response. Once a cell becomes infected with HSV the virus switches off host macromolecular synthesis. This also stops the production of new MHC molecules, therefore reducing the presentation of virus antigen to T cells. The virus has a more specific mechanism for the evasion of the CD8⁺ lymphocyte surveillance: an immediate early protein (ICP47) interferes with the peptide transporter (TAP) used to

move cytoplasmic peptides to the endoplasmic reticulum for complexing with MHC class I, thus reducing antigen presentation by infected cells. Additionally the virus produces both an immunoglobulin G Fc receptor (glycoprotein E $\pm$ glycoprotein I) and a complement C3b receptor (glycoprotein C) which are known to interfere with antibody and complement function protecting both virions and infected cells. HSV is known to encode genes which prevent apoptosis of differentiated cells, important in the infected neuron. Lastly and most importantly, HSV establishes a latent infection with no detectable protein expression which allows it to survive for many years in one host.

Vaccines

It is hoped that vaccination against HSV will protect from life-threatening infections and decrease recurrent episodes. Subunit glycoprotein (B-2 and D-2) vaccines have been studied in the guinea pig vaginal model and are known to reduce the frequency of recurrent infections. Unfortunately the avirulent or inactivated virus and subunit vaccines (glycoproteins B-2 and D-2) trialed in humans do not use placebo control groups and so any efficacy of the vaccines is hard to establish. Often antibody levels are unchanged after vaccination in the trial groups. The above vaccines are usually injected with alum but new adjuvants and ways of presenting antigen to the immune system are being investigated. Muramyl tripeptide appears to be a strong adjuvant. Delivery of antigen to the mucosal immune system is being studied using recombinant *Salmonella* or adenovirus. In animal trials, protection can be induced with glycoprotein D using recombinant *Salmonella* fed orally or intranasal administration of a glycoprotein B-expressing recombinant adenovirus. Direct DNA vaccination is also being studied with ICP27, glycoprotein B and D-2 genes. The type of immunity required for protection is not clear (see above) and it may prove that neutralizing antibody as well as T (CD4⁺ T_H1) lymphocytes will be important in

restricting the infection and perhaps in inhibiting the establishment of latent infections.

Finally, some of the most successful antiviral drugs are against HSV and these include acyclovir. Although these drugs cannot clear the latent infection once it is established, they can reduce the severity and length of productive infections.

Evasive strategies by the organism

HHV-6 infects cells of the immune system. A number of effects of such infection on cellular function have been described, although the *in vivo* significance of these phenomena are not clear. Virus-induced suppression of growth factor-induced maturation of marrow precursor cells and colony formation by marrow precursors may be important in inhibition of bone marrow engraftment following transplantation. Infection of peripheral blood lymphocyte cultures leads to interferon α , tumor necrosis factor α , and interleukin-1 β production, and suppression of T cell function as evidenced by reduced interleukin 2 synthesis and cellular proliferation. Infection of CD8⁺ T cells leads to expression of surface CD4, and resultant susceptibility to infection with HIV.

Vaccines

There are no reports as yet of attempts at development of protective vaccines.

HERPESVIRUS-8, INFECTION AND IMMUNITY

Thomas F Schulz, Department of Medical Microbiology and Genitourinary Medicine, The University of Liverpool, Liverpool, UK

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Human herpesvirus type 8 (HHV-8), or Kaposi's sarcoma-associated human herpesvirus (KSHV), is the first herpesvirus to be discovered by molecular biology techniques rather than by conventional tissue culture methods and probably represents the long-predicted infectious cause of Kaposi's sarcoma (KS).

Detection

Fragments of its genome were detected in 1994 by Chang *et al* using representational difference analysis (RDA), a polymerase chain reaction (PCR)-based technique involving subtractive hybridization and kinetic enrichment. HHV-8 genomes can be detected in all forms of KS, including human immunodeficiency virus (HIV)-associated KS, 'classic' KS in HIV-uninfected individuals. African 'endemic' KS (in HIV-uninfected individuals) and post-transplant KS. HHV-8 has also been found in a rare form of acquired immune deficiency syndrome (AIDS)-associated B-cell lymphoma, body cavity-based lymphoma (BCBL), or primary effusion lymphoma

(PEL), and in some cases of Castleman's disease. The detection of HHV-8 in other tumors from immunosuppressed individuals of Western countries has been reported by some, but not other groups. However, the significance of this finding remains to be established.

Relationship to other herpesviruses

HHV-8 is a γ_2 herpesvirus (rhadinovirus) and is the first human representative of this group. Several animal rhadinoviruses are known and some of them, herpesvirus saimiri (HVS), alcephaline herpesvirus 1 (AHV-1) and ovine herpesvirus 2 (OHV-2), cause lymphoid malignancies. Among human herpesviruses, HHV-8 is most closely related to Epstein-Barr virus (EBV), a γ_1 herpesvirus, which also causes lymphoid tumors in immunosuppressed individuals and may play a role in other malignant diseases (African Burkitt's lymphoma, Hodgkin's disease, nasopharyngeal carcinoma). While EBV-mediated cellular transformation has been studied in detail,

much less (with the exception of HVS) is known about the oncogenic mechanisms of rhadinoviruses.

Genome

HHV-8 genomes are present in KS spindle and endothelial cells, which are believed to represent the neoplastic component of this tumor. In KS tissue and in BCBL cells HHV-8 genomes are present as circular episomes and therefore probably persist in a latent form in these tissues. *In situ* hybridization studies using probes for latent HHV-8 genes have confirmed this conclusion. The HHV-8 genome contains several genes which could conceivably interfere with cell cycle control, cellular transcription or intracellular signaling; these include a bcl-2 homologue (orf 16), a cyclin D2-like protein (orf 72), an interleukin 6 (IL-6)-like protein (orf K2), chemokine homologs (orfs K4, K6), an interferon regulatory protein (orf K9), and a G protein-coupled receptor homolog (orf 74). The cyclin homolog is capable of interacting with cdk 6 to phosphorylate the retinoblastoma protein RB, and is expressed in KS tissue and in BCBL cells, but whether it, or any of the other viral proteins, plays a role in cellular transformation is not yet known and there is as yet no *in vivo* or *in vitro* evidence that HHV-8 is indeed a transforming rhadinovirus.

Does HHV-8 cause KS?

The epidemiological evidence for a causative link between HHV-8 and Kaposi's sarcoma is steadily accumulating. Detection of HHV-8 by PCR in peripheral blood correlates with, and predicts subsequent progression to, KS. Antibodies to a latent HHV-8 antigen and to a recombinant structural antigen are found in individuals with, or at risk for, KS but only rarely in healthy blood donors or members of those HIV risk groups (hemophiliacs, intravenous drug users) who are known to suffer from KS only exceptionally. Thus, the distribution of antibodies to these two HHV-8 antigens in Western countries mirrors that of KS, strongly suggesting a role for this virus in the pathogenesis of KS. Antibodies to the same HHV-8 antigens are more common in HIV-uninfected homosexual men and sexually transmitted disease clinic attenders than in the general population (blood donors). Among homosexual men in Northern Europe the likelihood of having antibodies to these defined HHV-8 antigens increases with the

number of partners and passive anal intercourse. As measured by these serological assays, HHV-8 was introduced into the homosexual community on a wider scale in the late 1970s/early 1980s. Infection with HHV-8 may, however, be more common in some Mediterranean countries and is very widespread in Africa. Thus, while HHV-8 may be a recently introduced sexually transmitted virus in some countries, it has existed for a long time in other populations, and 'classic' Kaposi's sarcoma was first described more than a century ago.

Prevalence in the general population

There is still considerable controversy about the prevalence rates of HHV-8. Antibodies to undefined structural HHV-8 antigens have been reported in up to 25% of North American blood donors, whereas antibodies to the recombinant capsid-related and latent HHV-8 proteins are found in 0–2% of North American and Northern European blood donors. Attempts to detect HHV-8 by PCR in peripheral blood and semen samples of healthy donors have yielded even more discrepant results. Some of these discrepancies may be the result of geographical variation in HHV-8 infection rates, but differences between assays probably also contribute.

HETEROPHILE ANTIBODIES

Felix Milgrom, Department of Microbiology, State University of New York, Buffalo, New York, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

In 1911, John Forssman noted that immunization of rabbits with guinea pig kidney leads to the formation of antibodies that act upon sheep erythrocytes. Forssman referred to this rather unexpected cross-reaction using the existing term 'heterologous reaction'. Subsequently, however, the term heterologous has been reserved for cross-reactions to be expected, such as between human and chimpanzee serum albumin for example. The term 'heterophile reaction' has been coined to denote unexpected cross-reactions. Accordingly, heterophile antibody is an antibody, the production of which was stimulated by an antigen apparently unrelated to the one with which this antibody cross-reacts. Heterophile antigen is, then, an antigen that reacts with such a heterophile antibody. There are many known heterophile antigen-antibody systems. Of these, three systems that are of significant interest for biology and medicine will be discussed. The antibodies defining these three systems have one important common feature – they all agglutinate sheep red blood cells.

The Forssman (F) system

The F antigen is the antigen originally described by Forssman as an antigen shared by sheep erythrocytes and guinea pig kidney. All the animal kingdom may be divided into F-positive species containing this antigen (guinea pig, hamster, mouse, sheep, goat, horse, dog, cat, chicken, etc.) and F-negative species (rabbit, rat, humans, apes, monkeys, ox, goose, etc.) which do not have this antigen. Interestingly, the appearance of F antigen in various animals does not parallel their genetic relatedness. Sera of F-negative species, notably rabbit and humans, frequently have naturally occurring F antibodies. The antigen shared by all F-positive animals is a glycosphingolipid, with a pentasaccharide being the active epitope. There is evidence that F antigen may appear in tumors of F-negative animals, including humans. Increased titers of F antibodies were noted in some patients with malignancies. Serologically characteristic is the disappearance of agglutination of sheep erythrocytes after absorption of the F antiserum by guinea pig kidney suspension, but not by bovine erythrocytes.

The Hanganutziu-Deicher (H-D) system

H-D antibodies were first described under the name 'serum sickness antibodies' by Hanganutziu in 1924,

and then by Deicher in 1926 in patients who received injections of sera of foreign species origin administered for serum therapy. Subsequently, H-D antibodies were found in human sera from many pathological conditions, though usually in low frequencies. H-D antigen is found in the tissues of all mammals studied to date, but it is absent from normal human tissues. On the other hand, it has been demonstrated in some human pathologic tissues, notably lymphoma and melanoma. Chemically, H-D antigen is an *N*-glycolylneuraminic acid, but many H-D-positive human sera contain antibodies combining with other antigenic moieties found in the high molecular weight glycoprotein fraction of sheep and bovine erythrocytes. Serologically characteristic is the disappearance of agglutination of sheep erythrocytes after absorption of sera containing H-D antibodies with bovine red blood cells as well as with guinea pig kidney suspension.

The Paul-Bunnell (P-B) system

Antibodies characteristic for infectious mononucleosis were described by Paul and Bunnell in 1932. These antibodies are predominantly of IgM variety. They are conveniently detected in reactions with sheep or bovine erythrocytes. Two antigenic moieties participating in these reactions could be distinguished: B, present on bovine erythrocytes only; and BS, appearing on both bovine and sheep erythrocytes. Most sera from patients with infectious mononucleosis contains antibodies against both B and BS, but a small proportion of IM sera with anti-B only was described. P-B antibodies appear in over 90% of patients with infectious mononucleosis but, significantly, they were hardly ever noted in patients with other pathological conditions or in normal subjects. The mode of formation of these antibodies in infectious mononucleosis is still not definitely explained. An attractive hypothesis postulates that they are formed in response to an antigen that is created in the course of the pathologic process. P-B antigen appears to be a glycoprotein. In serological tests, antibodies agglutinating sheep erythrocytes are removed from infectious mononucleosis sera by absorption with bovine erythrocytes, but not with guinea pig kidney suspension.

HIGH ENDOTHELIAL VENULES

Ann Ager, Division of Cellular Immunology, MRC National Institute for Medical Research, London, UK

High endothelial venules (HEVs) are specialized blood vessels which support the migration of naive lymphocytes from the bloodstream into secondary lymphoid organs. The majority of lymphocytes circulating in the blood are able to migrate into lymphoid organs via HEVs. This allows rare, antigen-specific lymphocytes to encounter small amounts of antigen on presenting cells within these organs and ensures effective surveillance of the body for antigen by the full repertoire of antigen-specific lymphocytes. The developmental origin of HEVs and their relationship to other types of blood vessel are not known. HEVs differentiate during neonatal life when the endothelial cells lining these blood vessels adopt a distinct, cuboidal morphology and express the peripheral and/or mucosal lymph node addressins. A precisely regulated sequence of adhesive interactions mediated by different families of adhesion molecules allows lymphocytes, but not other leukocytes, to adhere to the inner surface of HEVs which precedes their subsequent migration across the vessel wall and into the tissues. The peripheral and mucosal addressins, which are specific markers of HEVs are, in fact, cell adhesion molecules that mediate binding of lymphocytes to the surface of HEVs and, thus, they are critical for HEV function. Blood vessels with the morphology and adhesive properties of HEVs are found at sites of chronic immune-mediated inflammation and extranodal lymphomas. The development of these extranodal HEVs may exacerbate the disease process by facilitating the large-scale

migration of naive lymphocytes to nonlymphoid sites. Recent studies using transgenic techniques to direct the expression of inflammatory cytokines to extranodal sites have highlighted a role for cytokines in the development of HEVs at these sites.

What is an HEV?

Lymphocytes enter lymph nodes directly from the blood by migrating across the walls of specialized postcapillary venules which are located in the paracortex (T lymphocyte areas) of the node. These vessels have a characteristic morphology which distinguishes them from other types of blood vessel. The endothelial cells which line these vessels have a plump or cuboidal morphology, which contrasts to the flattened morphology of endothelial cells lining other types of vessel (**Figure 1**). It is the peculiar endothelial morphology that has engendered their common name – high endothelial venules (HEVs). The endothelial lining is surrounded by a thickened basement membrane, which is more pronounced than in other types of blood vessel. In immunocompetent adults, the localization of lymphocytes, but not other leukocytes, either attached to the inner (luminal) surface or within the vessel wall and the distinct morphological appearance are the most recognizable features of HEV. However, these vessels are also readily distinguishable from other blood vessels by histochemical, biochemical and immunological markers. The lining endothelial cells, which will be referred to as high endothelial cells (HECs),

Figure 1 Distinct morphological appearance of HEVs. Transmission electron micrographs of an HEV in peripheral lymph node (left) and a capillary in the vasa vasorum of aorta (right) of the rat. Note numerous lymphocytes (Ly) trapped in the walls of the HEV and increased height of lymph node high endothelial cells (HEC) in comparison with capillary endothelial cells (EC).

stain more intensely with RNA-binding dyes such as pyronin and contain a prominent Golgi apparatus and more secretory vesicles than other types of endothelia. Early histochemical studies also distinguished HEC from 'flat' endothelial cells lining other types of vessel. HEC express higher levels of nonspecific esterase, lactate dehydrogenase and NADH reductase. Biochemical studies identified a unique biosynthetic pathway for inorganic sulfate in HECs which is crucial for the generation of the peripheral addressin, an important adhesion molecule which mediates L-selectin-dependent binding of lymphocytes to HECs (see below). Several monoclonal antibodies have been described that specifically stain HEVs and not other types of blood vessel. These include MECA 79 and MECA 367, which identify the peripheral and mucosal addressins respectively, HECA 452, which identifies part of the functional carbohydrate epitope in the peripheral addressin, the sialyl Lewis^x saccharide and MECA 325, for which the antigen has not yet been identified.

The actual height of the endothelial cells lining HEVs varies between species and according to the method of tissue collection; therefore these vessels cannot be defined solely by endothelial height. For example, endothelial cells (ECs) which line equivalent vessels in lymph nodes of sheep, rabbits and guinea pigs are not as 'high' as those in rodents. Additional markers such as the expression of the vascular addressins are therefore important to identify these specialized blood vessels. Collection of rodent lymph nodes under reduced arterial pressure results in a constriction of the vessel lumen and plumping up of the endothelium to 15–20 μm in height. If the patency of HEVs is preserved by perfusion during fixation, then the endothelium is only 5–7 μm in height, although this is still greater than that lining

non-HEV blood vessels, which is 1–2 μm thick (Figure 1). The relationship between vessel patency and endothelial height suggest that HEVs are contractile vessels. Both the endothelial cell and the underlying basement membrane could contribute to HEV contractility. Dynamic changes in HEV morphology *in vivo* may enhance the trapping and passage of lymphocytes from the blood. The term HEV will be used to describe those postcapillary venules within lymph nodes which support the migration of naive lymphocytes from the blood irrespective of exact endothelial height.

Distribution

In adult animals, HEVs are normally found in lymph nodes, gut-associated lymphoid tissues such as Peyer's patches, and aggregates of lymphoid tissues associated with other mucosal surfaces such as bronchus-associated lymphoid tissue in the lungs. HEVs are not found in the spleen although lymphocytes continually migrate into this organ. Lymph nodes are highly vascularized organs and HEVs are found at precise locations within the microvascular bed of the lymph node (Figure 2). The main hilar artery feeding the lymph node arborizes into a capillary bed in the outer cortex which leads directly (or indirectly via arteriovenous shunts) into the postcapillary venular network. This traverses the paracortex (T cell area) of the node and HEVs are located within this postcapillary venular network. Several major HEV trunks, each receiving 3–5 smaller side-branches as they traverse the paracortex, are found within each node. In the medulla, HEVs merge into segmental veins before joining the hilar vein. The basic structure of HEVs does not differ between lymphoid tissues; however, there is heterogeneity among indi-

Figure 2 Location of HEVs within the lymph node. The main hilar artery into the lymph node arborizes into a capillary bed in the outer cortex which leads directly into the postcapillary venular network. This traverses the paracortex (T cell area) of the node and HEVs are located within this postcapillary venular network. Several major HEV trunks (30 μm in diameter) each receiving 3–5 smaller side-branches (9 μm in diameter) as they traverse the paracortex are found within a single node. In the medulla, HEVs merge into segmental veins before joining the hilar vein. Solid arrows denote transition from postcapillary venule lined with flat EC to HEV (i.e. postcapillary venule lined with high endothelial cells) and location of proliferating HECs in antigen-challenged node.

vidual HECs lining a single venule. The majority of HECs exhibit a basal level of activity but are interspersed with cells of increased cytoplasmic density due to abundant polyribosomes, dilated Golgi, and an invaginated luminal surface. This heterogeneity in metabolic activity is accompanied by varying levels of nonspecific esterase and 'hot spots' of enhanced lymphocyte extravasation. In contrast, expression of the vascular addressins is uniform on individual HECs within a single venule (see Figure 3).

HEV function in lymphocyte extravasation

To select sufficient antigen-specific lymphocytes for the initiation of immune responses, as many naive lymphocytes as possible should be sampled by antigen-presenting cells within lymphoid tissues. The clearly identifiable function of HEVs in this process is to recognize and sort lymphocytes from other leukocytes in the bloodstream and deliver them into lymph nodes. It is reasonable to assume that all of the HEV-associated properties described above may, in some way, regulate the selective migration of lymphocytes from the blood into the lymph node, but apart from the roles of individual adhesion molecules (see below) other properties have not been studied in relation to lymphocyte migration.

Structural considerations

The actual number of lymphocytes that migrate through a single node can be regulated in three ways: the extent of blood flow through HEVs, the size of the HEV network, and the rate of lymphocyte extraction per HEC. The level of lymphocyte migration through lymph nodes increases dramatically following antigen administration and a major contributor to this increased traffic is the rapid change in blood flow which can reach as much as three times control levels after 2 days. The rate of lymphocyte extraction is governed by the level of adhesion to and transmigration across the HEC layer. This can increase up to two-fold following antigen administration, which takes estimated extraction rates to a maximum of 60% of lymphocytes that flow through lymph nodes. The number of HECs, i.e. the size of the HEV network, also increases following antigenic stimulation and this will contribute to increased infiltration of lymphocytes. This increase occurs by endothelial proliferation but it is restricted to HECs at the boundary between 'flat' and high endothelium in the proximal region of the postcapillary venular network (see Figure 2).

Since the suggestion by Marchesi and Gowans that lymphocytes penetrated the HEC cytoplasm rather than taking a more conventional, intercellular pathway, the actual route of migration across the vessel wall has been a matter of debate. Ultrastructural studies have provided evidence in support of both intracellular and intercellular routes of lymphocyte migration. Scanning electron microscopic analysis of the luminal surface of HEV shows that HECs form a continuous lining and there are no obvious 'gaps' either between HECs or within HEC cytoplasm for lymphocytes to penetrate. Depending on the precise location in the HEV network, HECs are either

Figure 3 Organ-specific expression of the vascular addressins by HEVs. (A, C) The peripheral addressin (identified by monoclonal antibody MECA 79) is expressed by HEVs in (A) peripheral (cervical) and (C) mucosal (mesenteric) lymph nodes of adult BALB/c mice (solid arrows). (B, D) The mucosal addressin MAdCAM-1 (identified by monoclonal antibody MECA 367) is expressed by (D) mucosal lymph node (solid arrows) but not (B) peripheral lymph nodes HEVs (open arrows).

arranged in a cobblestone array (proximal segment) or as an interlacing network of cells (distal segment). However, all HECs have cytoplasmic extensions which overlap significantly with adjacent HECs. There are deep crevices in the luminal surface at these intercellular contacts and lymphocytes adhere preferentially at or near these junctions.

Lymphocytes undergo a dramatic change in morphology as they transmigrate the vessel wall. Circulating lymphocytes are spherical with numerous surface microvilli and they initially make contact with the surface of HECs via these microvillous projections. They then penetrate the HEC layer, during which the lymphocyte becomes polarized; this is accompanied by a loss of microvilli. During the migration of lymphocytes across the HEC layer very close intercellular, gap-like junctions of 2–4 nm are formed between lymphocytes and HECs, the significance of which is unclear. These are substantially closer than the 20–30 nm intercellular adhesive junc-

tions lymphocytes make with either the luminal surface of HEVs or the underlying basement membrane. Intercellular contacts between adjacent HECs are fewer in number than in other types of endothelia and they are limited to small areas of close apposition, referred to as 'spot welds'; this altered arrangement of inter-EC junctions may facilitate transendothelial migration of lymphocytes.

The potential role of the prominent basement membrane surrounding HECs in regulating lymphocyte extravasation warrants consideration. It comprises a layer of supporting cells (which are called pericytes in other types of blood vessel) embedded in a mixture of extracellular matrix molecules such as laminin, fibronectin and glycosaminoglycans. In addition a novel extracellular matrix glycoprotein has recently been demonstrated in HEVs. This protein, called HEVin, has homology to the antiadhesive extracellular matrix protein SPARC, and may play a role in regulating the morphology of HECs or the

permeability of the basement membrane. It is not clear whether the lymphocyte needs to degrade the basement membrane to cross it, but it does not appear to present a substantial barrier to lymphocytes. The basement membrane, but not the endothelial lining, is however, a barrier to small molecules in the blood stream. Following intravenous administration, soluble molecules accumulate on the endothelial side of the membrane. Conversely, molecules entering the node via the afferent lymphatics, somewhat surprisingly, have access to the intravascular compartment. There is evidence that the basement membrane underlying HEC is, in fact, an extension of the reticular network that extends throughout the paracortex of the node and that this network of reticular fibers, fibroblast reticular cells and extracellular matrix components functions as a conduit for bulk flow of soluble molecules from the afferent lymphatics to HEVs. This one-way traffic of soluble molecules from the node to the vascular compartment has been implicated in the transfer of chemoattractants that play a crucial role in regulating the adhesion of lymphocytes from flowing blood and subsequent transmigration across the vessel wall (see below).

Nonrandom migration of lymphocytes

The traffic of recirculating lymphocytes through lymph nodes in different regions of the body is not entirely random, which adds a further order of complexity to lymphocyte-HEV recognition. The most marked asymmetry is found between peripheral lymph nodes draining skin sites and lymphoid tissues associated with mucosal surfaces, such as Peyer's patches in the gut wall. Lymphocytes (T and B cells) collected from nodes draining either of these two sites in sheep preferentially migrate or 'home' back to their site of collection. In rodents, the discovery of lymphomas which adhere to either peripheral or Peyer's patch HEVs has identified a molecular basis for homing. Lymphocytes express 'homing receptors' that recognize ligands (termed 'vascular addressins') expressed by HECs in an organ-specific manner (Figure 3). The peripheral and mucosal homing receptors have been identified in mice as L-selectin and $\alpha_4\beta_7$ integrin respectively. Naive lymphocytes, which are randomly distributed between peripheral and mucosal lymph nodes, express both types of homing receptor. Following activation by antigen, L-selectin is downregulated from the lymphocyte surface and thus these cells lose the ability to migrate to peripheral lymph nodes. Selective expression of a mucosal homing receptor is presumed to form the cellular basis of the mucosal immune immunoglobulin A (IgA) response which occurs independently

of systemic immunity. Recent studies have demonstrated clearly that homing receptor/vascular addressin recognition represents just the first step in a sequence of adhesive interactions required for successful lymphocyte extravasation, that of binding to the inner surface of the HEVs from flowing blood.

The multistep adhesion cascade: roles of adhesion molecules and chemoattractants

A sequence of adhesive interactions, the multistep adhesion cascade, is required to arrest the lymphocyte from flowing blood on the inner surface of the HEV wall, prior to its directed migration across the vessel wall and into the lymph node. The adhesion cascade can be dissected into two distinct stages: a reversible, adhesive interaction that manifests as binding from flow and rolling on the inner surface of the vessel wall followed by a stable, adhesive interaction that completely arrests the leukocyte from blood flow (Figure 4: steps 1 and 2). Rolling is thought to allow the lymphocyte time to integrate and respond to stimuli presented on the endothelial surface which activate integrins and completely arrest the leukocyte on the vessel wall. Migration across the vessel wall (diapedesis) can also be dissected into distinct steps including transendothelial migration and migration across the underlying basement membrane (Figure 4: steps 3 and 4). Studies of lymphocyte migration have not distinguished between these steps and thus they are poorly understood. It is assumed that they are regulated by chemoattractants derived from the surrounding tissues which have access to the vascular compartment as described above.

The adhesion molecules which mediate lymphocyte rolling and stable adhesion in HEVs in Peyer's patches and peripheral (subcutaneous) lymph nodes of mice have been identified. L-selectin (the peripheral lymph node homing receptor) on the lymphocyte mediates binding from flow and rolling via recognition of sulfated, fucosylated, sialylated oligosaccharides (commonly called the peripheral addressin and identified in mice and humans by monoclonal antibody MECA 79) on proteins such as CD34, Sgp200 and GlyCAM-1 as well as MAdCAM-1 in Peyer's patches. L-selectin is less important in Peyer's patches where rolling is also mediated by $\alpha_4\beta_7$ integrin (the mucosal homing receptor) binding to MAdCAM-1 (the mucosal addressin). The subsequent stable adhesion of lymphocytes in all HEVs is mediated by the CD18 integrin, LFA-1, which requires a pertussis toxin (PTX)-sensitive activation step for its function. The stimuli that activate LFA-1 and lead to stable adhesion of lymphocytes, but not other types of leukocyte, on the

Figure 4 The sequence of events that regulate lymphocyte migration from the bloodstream across the walls of HEVs into lymphoid organs. Lymphocytes use L-selectin (and/or $\alpha_4\beta_7$ integrin in mucosal tissues) to roll on the HEC surface (step 1). Rolling is rapidly converted to integrin-dependent stable adhesion within 1–3 s (step 2). This is mainly mediated by LFA-1 following its activation via a pertussis toxin (PTX)-sensitive pathway. The ligands and activating stimulus for LFA-1 on the HEC surface are not worked out. Lymphocytes migrating to mucosal lymph nodes also bind via $\alpha_4\beta_7$ integrin recognition of MAdCAM-1. Transendothelial migration of bound lymphocytes (step 3) is regulated by a putative 'lymphocyte migration stimulus' expressed by HECs. The molecular basis of the final stage of migration across the basement membrane (step 4) is not understood but it is thought to be regulated by lymph node-derived chemoattractants.

inner surface of lymph node HEVs are undetermined. By analogy with the neutrophil, chemoattractant molecules operating on PTX-inhibitable G protein-linked receptors are likely candidates for this stage. Lymph node-derived chemoattractants have been proposed to direct the migration of lymphocytes across the HEV wall, although candidate molecules have not yet been identified. Since the majority of lymphocytes migrating into lymphoid organs are unactivated T and B lymphocytes, it is predicted that there are chemoattractants for these lymphocyte populations. Studies using cultured HECs suggest that transendothelial migration, the first step in diapedesis, can be initiated by the endothelial cells, suggesting that lymph node-derived chemoattractants may not be required for this step.

The crucial roles of L-selectin and β_7 integrins in directing lymphocyte migration to peripheral and mucosal lymph nodes respectively have been confirmed in 'knockout' mice; the requirement for fucosylation of the functional ligand for L-selectin on HEVs is also confirmed in mice in which the enzyme fucosyltransferase VII, which generates the sialyl Lewis^x modification has been deleted. This is, how-

ever, one of several post-translational modifications required to generate the peripheral addressin, the other being sulfation of sialyl Lewis^x and, possibly, other sugars. The endothelial selectins, E- and P-selectin, do not regulate lymphocyte migration via HEVs under basal conditions because they are not normally expressed by HEVs and the functional ligands for these two selectins are not expressed by naive T and B lymphocytes, which comprise the bulk of the migrating population.

HEV development

Morphologically distinct HEVs are not visible until birth in mice, rats and humans. Blood vessels expressing sialyl Lewis^x are detectable in lymphoid organs during embryonic life in humans; it is not clear whether these represent a precursor to HEVs which are not yet fully differentiated. Expression of the mucosal addressin is detectable at birth in mice, however its expression is widespread in both peripheral and mucosal lymph nodes. Expression of the peripheral addressin commences after birth and is accompanied by loss of MAdCAM-1 expression in

peripheral lymph nodes during the first few days of life. The peripheral addressin is, however, not strictly 'peripheral' since its expression is detectable in Peyer's patch HEVs in some mouse strains and migration to Peyer's patches is partially dependent on L-selectin.

The origin of HEVs is not clear. An obvious suggestion is that they are normal postcapillary venules in which the endothelial cells have been activated by their immediate microenvironment. Alternatively they be of a distinct developmental lineage arising from a different endothelial stem cell (Figure 5). Recent studies showing expression of a newly identified member of the endothelial cell-specific growth factor receptor family, FLT4, on HEVs and lymphatic endothelium, rather than on blood vessel endothelium, suggests the latter hypothesis. The developmental origin of cells in the basement mem-

brane of HEVs and their potential role in regulating the activity of the lining endothelial cells are also unknown.

In adult mice the expression of vascular addressins and the function of HEVs are actively maintained by, as yet, unidentified stimuli. Ligation of afferent lymphatics which drain into a lymph node from the surrounding tissues (Figure 2) has a dramatic effect on the phenotype and function of HEVs. Lymphocyte adhesion to HEV *in vitro* decreases dramatically and the migration of lymphocytes into lymph nodes *in vivo* is undetectable 3 weeks after deafferentization. Blood flow through the deafferentized lymph nodes is severely reduced, which limits lymphocyte entry *in vivo*. There is a gradual flattening of endothelial cells lining HEVs and a reduction in peripheral addressin expression. The components in afferent lymph which maintain fully functional HEVs and whether they have direct or indirect effects (e.g. via the underlying basement membrane) on HEVs are unknown. HEV morphology and function are normal in T and B lymphocyte-depleted mice (SCIDs, nudes and irradiated mice), which suggests that factors from accessory cells or the direct delivery of cytokines from surrounding tissues will be important. In congenitally athymic rodents, the endothelial cells lining peripheral lymph node HEVs are considerably flatter than in their euthymic litter mates. However, these blood vessels express the peripheral addressin and are able to support the migration of recirculating B and T cells. Thus the morphology and function of HEVs are independently regulated. HEVs in T cell-deprived mice acquire plump morphology on reconstitution with T cells. If the height of endothelial cells lining HEVs is related to vessel contractility (see above), this suggests that HEV contractility may be regulated by T cells or their products.

Figure 5 Developmental origin of HEVs. *Nodal*: In lymph nodes HEVs may arise from uncommitted postcapillary venules which have undergone a normal developmental program in response to EC-specific growth factors or from a distinct high endothelial stem cell. The morphology, expression of vascular addressins and ability of HEVs to support the migration of lymphocytes is maintained by components gaining access to the node via afferent lymph. *Extranodal*: HEV-like vessels expressing vascular addressins may represent uncommitted blood vessels in which the endothelial cells have been activated by locally produced cytokines or may arise from a distinct high endothelial stem cell which proliferates during the angiogenic response associated with chronic inflammation. The developmental origin of cells in the basement membrane of HEVs is unknown.

Extranodal development of HEVs: relationship between high endothelium and other types of vascular endothelium

Blood vessels with the distinct morphology, biochemical properties, and antigenic profile of HEVs have been reported at sites of chronic immune-mediated inflammation, such as in rheumatoid synovia, the pancreas of NOD mice and in rejecting allografts. Blood vessels in the lamina propria of mice express the mucosal addressin MADCAM-1 and the HEC-specific antigen MECA 325, although they do not have the morphology of HEVs. As in lymph nodes, it is not clear whether these extranodal HEVs are formed from existing vessels via a response of the endothelial cells to local inflammatory mediators, or

whether they are formed *de novo* from a distinct progenitor cell during the angiogenic response associated with chronic inflammation (Figure 5). HEV-like properties have been reported in peritubular capillaries of the rat within 3 days of transplantation of fully allogeneic kidneys, indicating that microvascular changes can be rapid and are not restricted to postcapillary venules.

Studies using transgenic techniques to direct the expression of cytokines to extranodal sites demonstrate a role for cytokines in the formation of HEV-like vessels at these sites. Expression of interferon γ (IFN γ), tumor necrosis factor α (TNF α), lymphotoxin α (LT α) and interleukin 10 (IL-10) in islets of Langerhans in the pancreas of mice induces HEV-like blood vessels expressing the peripheral and mucosal addressins. The formation of HEV-like vessels correlates with the accumulation of unactivated T and B lymphocytes within these organs. It is not clear whether these cytokines have direct or indirect effects on blood vessels, however, some HEV-associated properties can be induced in nonlymphoid vascular endothelium in response to cytokine stimulation *in vitro*. IFN γ induces expression of the MECA 325 antigen and TNF α induces expression of MAdCAM-1 on murine endothelial cell lines. Induction of the peripheral addressin on cultured endothelial cells has not, however, been demonstrated. Studies in cytokine gene 'knockout' mice do not support roles for IFN γ or TNF α in the normal developmental program of HEVs. However, lymph nodes fail to develop in the absence of LT α or following blockade of the LT β R, which binds a cell surface LT α /LT β complex. It is possible that LT β R interactions regulate the development of lymph nodes via a direct effect on the vasculature inducing HEVs in embryonic life or by promoting the formation of the lymph node anlage, the precursor to lymph node formation, which may itself direct HEV development. The effects of IFN γ and TNF α at extranodal sites may therefore be exerted via indirect effects on the expression of either LT α / β complex or LT β R. The capacity of afferent lymph to affect HEV function is not dependent on this signaling pathway since once lymph nodes have formed they are unaffected by LT β R blockade.

Summary

What then is the function of HEV? The answer will depend on which HEV-associated property is under consideration. During the development of the immune system, HEVs are crucial for its formation and function in that they localize recently matured

T and B lymphocytes to secondary lymphoid organs. The unique structure of HEV provides an efficient collector of lymphocytes from the blood in that rapid changes in blood flow, trapping and migration of lymphocytes are facilitated. The migration of lymphocyte subsets to different regions of the immune system via organ-specific vascular addressins suggests that HEVs can directly affect the outcome of a local immune response. Finally, HEV-like vessels at sites of chronic inflammation will promote the immigration of naive lymphocytes and thus may amplify and maintain ongoing immune responses. Identification of the stimuli that induce HEV formation at these sites may, therefore, provide a means of controlling chronic immune-mediated inflammation.

HISTAMINE

Frederick L Pearce, Department of Chemistry, University College London, London, UK

The biogenic amine histamine has long been incriminated as an essential mediator in immediate type I hypersensitivity and anaphylactic reactions. However, the amine also regulates the activity of other immune cells and has a fundamental role in the control of gastric acid secretion, the central nervous system and cell proliferation and cancer.

Chemistry, metabolism and distribution

Histamine (1*H*-imidazole-4-ethanamine) is formed by the decarboxylation of the amino acid histidine. There are two major pathways for the catabolism of the amine in humans (Figure 1). The most important route involves ring methylation and is catalyzed by the enzyme histamine-*N*-methyltransferase. The product, *N*^τ-methylhistamine, is then largely converted by monoamine oxidase to *N*^τ-methylimidazole acetic acid. In the second pathway, histamine is oxidatively deaminated to imidazole acetic acid by the enzyme diamine oxidase. The latter is also known as histaminase. The various metabolites have little or no pharmacologic activity and are excreted in free or in conjugated form in the urine.

Histamine is widely distributed throughout the various tissues of the human body; the name derives from the Greek word for tissue, *histos*. Every mammalian tissue that contains the amine is capable of synthesizing it from histidine by virtue of L-histidine decarboxylase. In most tissues the bulk of the amine is stored in the secretory granules of mast cells. In the blood, histamine is contained in the circulating counterpart of the mast cell, the basophil leukocyte. Histamine and other inflammatory mediators are released by the immunological activation of these cells in the course of immediate hypersensitivity reactions and thereby contribute to the symptoms of allergy and anaphylaxis. Histaminergic neurons of the central nervous system constitute an important non-mast cell source of the amine in humans (see below).

Histamine receptors

Histamine acts on a large variety of different cell types, including smooth muscle cells, neurons, endocrine and exocrine cells, blood cells and cells of the immune system. The biological effects produced are mediated through distinct receptors of which three subtypes, designated H₁, H₂ and H₃ respectively, have now been identified. Activation of H₁-receptors appears to lead to the breakdown of membrane inositol phospholipids and the consequent generation of diacylglycerol and the mobilization of calcium ions. The latter then act as second messengers for transduction of the biological response. In contrast, H₂-receptors are coupled to adenylate cyclase and actions of histamine at these sites are mediated through a rise in the intracellular level of cyclic AMP. The genes for the H₁ and H₂ receptors have been cloned and show limited homology, suggesting that they are not derived from a common ancestral precursor.

H₃ receptors are located on presynaptic nerve endings of histaminergic and nonhistaminergic neurons in the brain. The second-messenger system associated with these receptors remains to be fully elucidated but they function as autoreceptors and heteroreceptors to regulate the release of histamine and other central neurotransmitters.

Responses mediated through H₁ receptors are antagonized by classical 'antihistamines' such as mepyramine and chlorpheniramine, those through H₂ receptors are antagonized by cimetidine and ranitidine, and those through H₃ receptors by thioperamide.

Pharmacologic effects

Localized allergic reactions to food or aeroallergens are generally confined to particular target organs, such as the airways, eye, gut and skin. However, more generalized, systemic responses may occur, typically in anaphylactic or anaphylactoid reactions to various drugs, agents used in surgical or proper-

Figure 1 Synthesis and catabolism of histamine.

ative procedures such as anesthetics and their vehicles, plasma substitutes and radiographic contrast media, and to certain insect stings, particularly those of the bee.

Anaphylactic reactions in humans are accompanied by a sharp rise in the plasma concentration of histamine and the classical signs of intoxication by the amine. The clinical manifestations may vary considerably in severity. Mild cutaneous reactions involving erythema, urticaria and pruritus, often accompanied by metallic taste, headache and nasal congestion, are associated with plasma histamine levels below 1 ng ml^{-1} . Systemic responses with generalized skin reactions, discomfort, gastrointestinal disturbance, tachycardia, cardiac arrhythmias and medium hypotension involve elevations in plasma histamine above this basal level. Life-threatening responses comprising severe hypotension, ventricular fibrillation, bronchospasm and cardiac and respiratory arrest are typically associated with

plasma histamine levels in excess of 12 ng ml^{-1} (Table 1). These responses may be most conveniently discussed in terms of the various systems involved.

Cardiovascular system

The hemodynamic response to histamine involves an effect of the amine on the blood vessels and a direct action on the heart. In humans, and most but not all other animals, histamine has a predominantly dilator effect on the peripheral blood vessels. This dilatation results in a characteristic flushing, a decrease in total peripheral vascular resistance and a fall in blood pressure. Both H_1 and H_2 receptors appear to be involved in these responses, with H_1 receptors largely mediating the initial vasodilator effect and H_2 receptors becoming progressively involved during sustained exposure to the amine.

The above, and an important additional effect, are involved in the so-called 'triple response' produced by intradermal injection of histamine. This response

Table 1 Classification of histamine-mediated systemic responses by severity

Severity grade	Clinical symptoms	Plasma histamine (ng ml ⁻¹)
I: Cutaneous	Erythema, urticaria and/or dermal pruritus <i>only</i>	≤ 1
II: Systemic	Generalized skin reactions, discomfort, tachycardia, arrhythmias, medium hypotension, respiratory distress	> 1
III: Life-threatening	Severe hypotension, ventricular fibrillations, cardiac and respiratory arrest	> 12

Adapted from Ennis M and Lorenz W (1985) Hypersensitivity reactions induced by anaesthetics and plasma substitutes. In: Dean J (ed) *Immunotoxicology and Immunopharmacology*, pp 457–474. New York: Raven Press.

comprises a localized red spot, which is confined to a few millimeters around the site of injection and which develops within a few seconds, a flare of irregular outline that extends several centimeters beyond the original point of injection and develops more slowly, and a wheal that is discernable within 1–2 min and occupies the same area as the original red spot. The red spot results from the direct vasodilatory effect of histamine, while the wheal is due to an increase in capillary permeability and edema formation. The flare response is more complex and involves an axon-reflex mechanism whereby histamine stimulates afferent C-fiber nerve endings. The resulting impulses may spread antidromically into arborizations of the C fiber, leading to the release of neuropeptides, such as substance P, which act directly on the vasculature to propagate the inflammatory response.

In the human heart, histamine increases both the frequency and force of myocardial contraction as well as cardiac output. The amine also has a variety of arrhythmogenic effects, including enhancement of normal automaticity, induction of abnormal automaticity, induction of triggered tachyarrhythmias, depression of atrioventricular conduction and an increase in the vulnerability of the ventricles to fibrillation. A combination of H₁- and H₂-directed antihistamines is needed to block this diversity of effects, indicating the involvement of both receptor types. Although somewhat controversial, both the positive inotropic and chronotropic effects of histamine appear to be largely mediated through H₂ receptors, although H₁ receptors may additionally be involved in the former response.

Nonvascular smooth muscle

The effect of histamine on various types of smooth muscle varies according to the source and the species; however, the amine typically contracts nonvascular smooth muscle through activation of H₁ receptors, although occasional relaxant responses, largely mediated through H₂ receptors, are observed.

Inhalation of histamine in humans leads to bron-

choconstriction. This effect is most pronounced in asthmatic subjects in which the dose of histamine (PC₂₀ histamine) required to produce a 20% reduction in the forced expiratory volume in 1 second (FEV₁) is widely used as a measure of the degree of bronchial hyperreactivity. The initial bronchoconstrictor response to inhaled allergen in humans appears to be largely due to mast cell activation, with at least half of the effect being produced by the release of histamine and the remainder by the liberation of arachidonic acid metabolites. Among experimental animals, bronchial smooth muscle of the guinea pig is exquisitely sensitive to histamine and a profound, fatal bronchoconstriction is the characteristic feature of anaphylaxis in this species. Unusually, histamine causes relaxation in the sheep bronchus and cat trachea.

The response of gastrointestinal smooth muscle also varies with the species; however, the classical effect is again contraction and this response in the terminal ileum of the guinea pig forms the basis of the original bioassay for histamine.

Gastric acid secretion

Histamine plays an essential role in the regulation of acid secretion by oxyntic cells in the stomach. The source of this histamine varies according to the species but in humans the amine is located largely in mast cells in the gastric mucosa. The control of acid output is complex, with neurocrine, endocrine and paracrine factors acting together in interdependent fashion. In particular, acetylcholine, gastrin and histamine modulate the release process.

Two theories have evolved to account for the control of acid secretion. In the 'permission hypothesis', the oxyntic cells express acetylcholine, gastrin and histamine (H₂) receptors on their surface, with the effects of acetylcholine and gastrin only being fully expressed if the histamine receptors are occupied. That is, the former agents act by 'permission' of histamine. In the 'transmission hypothesis', histamine is the final common chemostimulant for secretion, and bloodborne gastrin and neurally released acetylcho-

line act on mast cells located adjacent to the oxyntic cells to induce release of the amine. The secreted histamine then acts through H_2 receptors on the oxyntic cells to cause the release of acid. Histamine thus 'transmits' the actions of acetylcholine and gastrin. Of these two models, the permission hypothesis has probably received general acceptance although the transmission hypothesis has recently been vigorously revived. In any event, histamine clearly plays a key role in the process and H_2 antihistamines are potent inhibitors of acid secretion induced by all physiologic mechanisms. Clinically, these agents have revolutionized the treatment of peptic ulcer disease.

The central nervous system

There are two major cellular sources of histamine in the human brain, namely mast cells and histaminergic neurons. The mast cells occur in the largest numbers in those brain structures with a high degree of vascularization, such as median eminence, the pineal gland and the meninges. They are found in close association with blood vessels and may play a role in the control of brain blood flow and vascular permeability. Histaminergic neurons are confined exclusively to the tuberomammillary nucleus in the posterior hypothalamic region. Individual neurons project axon collaterals to many different areas and essentially innervate the whole brain. These morphologic features suggest that the central histaminergic system provides a regulatory centre for whole-brain activity. Indeed pharmacologic studies using histamine agonists, antagonists and inhibitors of the synthesis of the amine have suggested that histaminergic neurons may control the sleep-wakefulness cycle, feeding and drinking behaviours, locomotor activity, the neuroendocrine system, body temperature and circulation. Brain histamine may also be involved in aging, neurodegeneration and dementia.

Cell proliferation and cancer

It has been known for many years that histamine may promote wound healing and that proliferating tissues synthesize the amine at a very high rate. Various treatments capable of stimulating cell proliferation in the skin, such as mechanical trauma or topical application of phorbol esters and detergents, also induce local histamine synthesis. The time of maximal epidermal hyperplasia coincides with a significant increase in the tissue level of the amine and a sharp fall in the activity of the histamine-catabolizing enzyme diamine oxidase. The proliferative effect of histamine may be mediated through a novel intracellular receptor (H_{IC}).

Newly formed, nascent histamine may also be involved in tumor growth and development. High

levels of the amine and of its synthesizing enzyme histidine decarboxylase are found in growing tumors in experimental animals, and an increased activity of the enzyme has been reported in both human mammary and colorectal carcinoma tissues. In contrast, diamine oxidase activity is diminished in the latter tissue compared with the surrounding colonic mucosa. Often, the histamine concentration in the tumors does not parallel the histidine decarboxylase activity, probably indicating the rapid release or metabolism of the amine. Significantly, inhibitors of histidine decarboxylase produce a marked inhibition of tumor growth in different animal models.

The above data would suggest a positive role for histamine in tumor induction. Consistently, studies in laboratory animals have indicated that administration of H_2 -receptor antagonists may lead to a decreased tumor growth and metastatic development, and an increased survival time. However, H_1 antihistamines promote the growth of some tumors, and abolish the antitumoral effect of the H_2 blockers, while selective H_1 -receptor agonists can again inhibit tumor development.

These apparently confusing findings may be rationalized into a convenient working model in which histamine plays a dual role in carcinogenesis. During tumor growth, newly synthesized histamine exerts an immunosuppressive effect by activating host suppressor T lymphocytes through H_2 receptors on the cell surface (see below). H_2 antagonists may block this activation and facilitate the natural immune response to, and destruction of, the tumor cells. In parallel, histamine, or appropriate experimental agonists, may exert an immunostimulatory effect by activating T contrasuppressor or effector cells through H_1 receptors. Blockage of this potentially beneficial effect by H_1 antihistamines would promote tumor development. In addition, H_1 and H_2 receptors have recently been described on different tumor cells and histamine could then directly regulate proliferation by acting on these receptors.

Cells of the immune system

The role of histamine in allergy and atopy is well established. As discussed, the amine is released from tissue mast cells and circulating basophil leukocytes by immunoglobulin E (IgE)-dependent mechanisms. This release may be modulated by histamine H_2 autoreceptors which appear to be present on the surface of the human basophil but not the lung mast cell.

In addition, histamine may have a more general role in the regulation of both humoral and cell-mediated immune responses. The amine suppresses lymphocyte proliferation, T cell-mediated cytotoxic-

ity of allogeneic target cells, and lymphokine production. All of these effects appear to be mediated through H₂ receptors. Histamine also suppresses the production of antibodies by B lymphocytes, natural killer cell cytotoxicity, complement production by monocytes, lysosomal enzyme release by neutrophils and neutrophil chemotaxis. Thymocyte maturation, eosinophil chemotaxis and expression of eosinophil complement receptors are also affected.

HISTOPLASMA, INFECTION AND IMMUNITY

George S Deepe Jr, Division of Infectious Diseases, Department of Medicine, University of Cincinnati College of Medicine, Cincinnati, Ohio, USA

Characteristics of *Histoplasma capsulatum* and its antigens

The pathogenic fungus, *Histoplasma capsulatum*, exists in nature as a filamentous organism that produces two asexual spores, microconidia and tuberculate macroconidia. The natural habitat of the organism is soil enriched by bird droppings. Chromosomal mapping studies of this fungus have revealed substantial variability in the genomic organization of *H. capsulatum* strains. The Downs strain, which is thermointolerant, possesses seven chromosomes, whereas two thermotolerant strains, G217B and G186B, contain three and four chromosomes, respectively. Thus, a small number of chromosomes regulate a considerable number of biological events.

Infection is acquired via inhalation of microconidia or small mycelial fragments that settle in terminal bronchioles and alveoli of lungs. Within a period of hours to days, these fungal elements convert into yeasts which represent the tissue-specific phase. The transformation of mycelia to yeasts is

accompanied by an orderly sequence of biochemical events that can be divided into three stages. Initially, there is a reduction in the intracellular levels of adenosine triphosphate and a decrease in the respiratory rate of mycelia. In the second stage, the cells enter a dormant phase for 4–6 days. Subsequently, the rate of respiration returns to normal, and there is an induction of a yeast phase-specific cysteine oxidase. At this time, the morphological switch to yeasts is completed.

Phase transition is also associated with several alterations in gene expression. One to three hours after a temperature shift from 25 to 37°C, there is a marked increase in the expression of the genes encoding heat shock protein 70 and *cdc2*, which is a regulator of cell division. On the other hand, conversion of mycelia to yeasts produces a 2–3-fold reduction in expression of α -tubulin and β -tubulin mRNAs. A yeast phase-specific gene, *yps3*, is expressed only by strains that are thermotolerant and virulent. The avirulent Downs strain contains a 287 bp insertion that

disrupts the open reading frame of *yps3*. A precise function for this gene and its protein product has not been defined. It is likely that it regulates, at least partially, the morphological conversion of *H. capsulatum*.

Infection of humans with *H. capsulatum* is usually asymptomatic or it produces an influenza-like illness. A small percentage of individuals will develop a cavitary pulmonary disease or a disseminated infection that extensively involves the reticuloendothelial system. Although cases of histoplasmosis have been reported worldwide, the endemic areas are the Ohio and Mississippi river valleys in North America, and Central and South America. It is estimated that 200 000–500 000 new infections occur annually. Disseminated histoplasmosis has become a prominent cause of morbidity and mortality in patients with acquired immune deficiency syndrome or in those receiving potent immunosuppressive agents.

The originally described *H. capsulatum* antigens consisted of the culture filtrate of aged mycelia, otherwise known as histoplasmin, and yeasts treated with formalin. Histoplasmin is currently the principal antigenic mixture that is employed for analysis of both humoral and cell-mediated immune responses in humans and experimental animals infected with *H. capsulatum*. This preparation contains two glycoprotein antigens, M and H, which elicit both cell-mediated and antibody responses and a carbohydrate moiety, termed C antigen, which is recognized by circulating antibody from infected humans. The gene encoding H antigen has been cloned, and the deduced amino acid sequence indicates that the protein is homologous to extracellular β -glucosidase. M antigen appears to be a member of the catalase family. The carbohydrate portions of M and H antigens and the C antigen are rich in mannose and galactose. *In vitro* studies have shown that deglycosylation of M and H sharply reduces the capacity of these antigens to stimulate *Histoplasma*-reactive T cell clones. Antibody to C antigen can cross-react with antigens from heterologous fungi including *Blastomyces dermatitidis* and *Coccidioides immitis*.

Numerous other preparations of antigens have been isolated from disrupted mycelia and yeasts or from supernatants of actively growing organisms. Because much of this effort has been applied to improving serologic diagnosis of histoplasmosis, biochemical characterization of antigens has centered on identifying determinants that are recognized by circulating antibody. Polysaccharide determinants that contain galactomannan or glucomannan often react with sera from patients infected with *H. capsulatum*. More recently, several antigens that stimulate a cell-

mediated immune response have been identified. Heat shock protein 60, an 80 kDa protein with homology to heat shock protein 70, and *yps3* stimulate proliferation of lymphocytes by *H. capsulatum*-exposed mice or humans.

The organism does not secrete any known virulence factors. However, the α -(1,3)-glucan content in the cell wall of yeasts appears to correlate directly with virulence. Thus, avirulent variants contain up to 1000-fold less α -glucan than virulent parental strains.

Immune responses of the host

It is generally acknowledged that cell-mediated immunity is the critical host defense mechanism triggered in response to infection with this fungus. In humans, the specific cellular immune responses are believed to be activated in lymphoid organs and other tissues 7–18 days after exposure to conidia. Concomitant with stimulation of cellular immunity, the lesions in organs begin to heal. Granulomas are formed, with necrosis developing in the central portion. Lymph nodes draining the sites of infection enlarge, resolve by encapsulation, and then may calcify. *In vivo* or *in vitro* delayed-type hypersensitivity responses to histoplasmin can be detected approximately 4 weeks after infection.

H. capsulatum is a facultative intracellular pathogen that parasitizes macrophages and neutrophils. Resting mononuclear phagocytes provide an intracellular milieu that allows the yeast form not only to survive but also to replicate. Unopsonized yeasts and conidia bind to epitopes of the lymphocyte function-associated antigen 1 (CD11a/CD18), complement receptor type 3 (CD11b/CD18), and the p150–95 complex (CD11c/CD18) of adhesion-

Figure 1 Circulating polymorphonuclear leukocyte infected with *Histoplasma capsulatum* yeast cells from a patient with human immunodeficiency virus infection. (With permission from Judith Rhodes.)

promoting receptors on human monocyte-derived macrophages and alveolar macrophages. Binding of yeasts to phagocytes is rapid and requires divalent cations. Once ingested, unopsonized yeasts trigger production of hydrogen peroxide by human macrophages. By contrast, *Histoplasma* yeasts fail to stimulate a respiratory burst as measured by ferricytochrome *c* reduction when phagocytosed by murine peritoneal macrophages. Ingestion of yeasts prompts phagosome-lysosome fusion. Within the phagolysosome, the yeast raises the intracellular pH to approximately 6.0–6.5. This elevation presumably enhances survival of the fungus intracellularly because it blunts the activity of acid proteases. The pH must be tightly regulated because the organism must scavenge iron from the intracellular contents of macrophages.

Both protective immunity and delayed-type hypersensitivity are transferred by antigen-specific CD4⁺ T cells. *In vitro*, antigen-reactive murine T cells undergo blastogenesis in response to *Histoplasma* antigens and secrete several lymphokines including interferon γ (IFN γ). CD8⁺ T cells also contribute to protective immunity. Depletion of these cells by monoclonal antibody to CD8 from mice impairs clearance of the fungus. However, the mice recover. In contrast, mice whose CD4⁺ T cells are eliminated by administration of monoclonal antibody to CD4 die after challenge with a sublethal inoculum. Thus, both T cell subpopulations participate in host defence, but CD4⁺ T cells appear to play a more pivotal role.

In mice, several cytokines appear to influence the outcome of infection in naive animals. The monokines, interleukin 12 (IL-12) and tumor necrosis factor α , are crucial determinants of survival of infected mice. IL-12 appears to act through induction of IFN γ . Depletion of IFN γ renders mice incapable of controlling infection. In contrast, anti-IL-4 treatment of mice inoculated with a lethal challenge of yeasts improves survival. The action of IFN γ is thought to be key in stimulating the anti-*Histoplasma* activity of macrophages. In this regard, recombinant murine IFN γ activates peritoneal macrophages from mice to inhibit but not kill intracellular yeasts. The finding that macrophages exert fungistasis rather than a fungicidal effect is of major clinical significance as yeasts are believed to remain viable, albeit in a dormant state, in tissues for many years.

However, human IFN γ does not arm human macrophages to express an anti-*Histoplasma* effect. The cytokines IL-3, granulocyte-macrophage colony-stimulating factor and macrophage colony-stimulating factor activate human macrophages to inhibit the

growth of yeast cells. Thus, there is an apparent disparity between human and murine macrophages.

Evasive strategies by the organism

Transformation of conidia to yeasts is one mechanism by which the fungus adapts for survival. Once inside mononuclear phagocytes, yeasts may decrease the release of toxic oxygen products. Additionally, yeasts are markedly more resistant to the microbicidal effect of hydrogen peroxide than are conidia. How the yeast escapes killing is not known.

Infection with this fungus can perturb cellular immune responses. In experimental animals or humans with disseminated histoplasmosis there is a considerable impairment of delayed-type hypersensitivity responses and *in vitro* proliferative responses to mitogens and antigens. In mice with disseminated disease, diminished reactivity is associated with the presence of CD8⁺ suppressor cells and a suppressor macrophage-like cell in spleens and lymph nodes of infected animals. These CD8⁺ T cells release a suppressor factor that inhibits cellular immune responses *in vitro*. Poor responses also may be secondary to defective production of IL-1 and IL-2, two cytokines that are critical in the amplification of T cell-mediated immunity.

Vaccines

No licensed vaccine exists yet. However, recent work with *H. capsulatum* heat shock protein 60 indicates that this molecule can function as a possible vaccine candidate. The native as well as the recombinant antigen can confer protection to mice with pulmonary histoplasmosis. There is evidence an oligopeptide from this protein confers protection when used as a vaccine. Additional studies are seeking to determine if a peptide from heat shock protein 60 can mediate protection.

HLA CLASS I

Xiaohua Wei and Harry T Orr, Institute of Human Genetics, Minneapolis, USA

A multigene family

The human major histocompatibility complex (MHC) is designated the human leukocyte antigen (HLA). This genetic region is located on the short arm of chromosome 6, and consists of genes that encode three classes of molecules, HLA class I, class II and class III.

To date, the most extensively characterized members of the HLA class I gene family are the genes encoding the major transplantation antigens, HLA-A, -B and -C, also termed the classical class I genes. A genetic map of the short arm of chromosome 6 based on recombination fractions places HLA-B 0.2 cM (centiMorgan) proximal of HLA-C, and HLA-A 0.8 cM distal to HLA-C. These genes encode highly polymorphic 44 kDa antigens that are non-covalently associated on the cell surface with an invariant 12 kDa subunit, β_2 -microglobulin (β_2 m). The gene encoding β_2 m is located on chromosome 15. Class I heavy chain genes consist of eight exons. Exon 1 encodes the hydrophobic leader peptide. The second, third, and fourth exons encode the extracellular $\alpha 1$, $\alpha 2$ and $\alpha 3$ domains respectively. The transmembrane domain and the first five amino acids of the cytoplasmic region are encoded by exon 5. The remainder of the cytoplasmic segment is encoded by exons 6–8.

Molecular genetic studies indicate that the HLA-A, -B and -C genes represent only a small subset of an extensive gene family. There are approximately 17 HLA class I genes per haploid genome. Most of these are HLA class I pseudogenes that do not seem to be capable of encoding an expressed HLA molecule. Three non-HLA-A, -B -C class I genes which are expressed have been isolated. These are designated HLA-E, -F and -G. Sequence analysis of these three class I genes shows that each is intact and encodes a class I heavy chain that can associate with β_2 m.

Each gene has intact exons 1–5, i.e. the leader peptide through the transmembrane domain.

The HLA-E gene is located between the HLA-A and HLA-C genes. The HLA-F and HLA-G genes are located distal to HLA-A. In the HLA-E gene, there is a deletion of five nucleotides from exon 7, resulting in an in-frame termination codon, and a class I protein one amino acid shorter than most HLA-B molecules and four amino acids shorter than most HLA-A chains. The HLA-F gene differs from other class I genes in that the 3' splice recognition site of intron 6 has a variant dinucleotide sequence: AA instead of the conserved AG sequence. This alteration in the 3' splice site of intron 6 in HLA-F results in the removal of nucleotides within exon 7 of HLA-F during mRNA processing. Thus, the HLA-F protein has a cytoplasmic segment shorter than that of the HLA-A, -B and -C class I genes. The HLA-G gene also differs from other class I genes in that an in-frame termination codon is located at the second codon of exon 6. Thus, most of exon 6 and all of exons 7 and 8 are not translated into the HLA-G protein.

Patterns of HLA class I gene expression

HLA-A, -B and -C genes are expressed on virtually all nucleated cells. The amount of expressed antigen varies considerably, depending on the cell type and the HLA class I locus, with lymphocytes expressing the highest levels of HLA-A, -B and -C antigens. Among lymphocyte subsets, B lymphocytes express HLA-A, -B and -C antigens at a higher level than T lymphocytes, and immature T lymphocytes express a relatively lower level of HLA-A, -B and -C antigens than mature T lymphocytes. Northern blot analysis indicates that the difference in HLA-A, -B and -C gene expression of B and T lymphocytes is reflected by the steady-state level of HLA class I mRNA. There is a considerable variation in the level of

expression between different class I loci within the same cell type. HLA-C products are found at the cell surface at about one-tenth the amount of HLA-A and HLA-B molecules.

Some factors that modulate the immune response have been shown to affect the expression of the HLA class I antigens in various cell types. Interferons α , β and γ increase the expression of HLA-A, -B and -C antigens and β_2m in fibroblasts and lymphoblastoid cells. This increase in antigen expression is preceded by an increase in class I and β_2m mRNA. Tumor necrosis factor (TNF) is another immune modulator that enhances HLA class I expression. *In vitro*, human TNF has been shown to increase the mRNA level and cell surface expression of HLA-A, -B and -C antigens in normal human vascular endothelial cells and dermal fibroblasts. Both interferon and TNF have a role in the enhancement of cytotoxic T lymphocyte lysis of virus-infected cells by their ability to increase the transcription and the antigen expression of HLA class I genes.

Each of the HLA-E, -F and -G genes have been shown to encode an HLA class I heavy chain after DNA-mediated gene transfer studies. HLA-E, -F and -G genes have been studied following their transfer into a HLA-A, -B, -C-null B lymphoblastoid cell line (B-LCL 721,221). The B-LCL transfected with cloned HLA-G DNA became positive at the cell surface for binding of a monoclonal antibody (mAb) to monomorphic determinants of class I antigen, w6/32, and binding of an anti- β_2m mAb, BBm.1. Binding of these mAbs was not detected on the B-LCL after transfection with either the HLA-E or the HLA-F DNA. However, sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) analysis of immunoprecipitates with w6/32 and BBm.1 showed that lysates from the B-LCL cell line transfected with HLA-E and HLA-F DNA contained a class I heavy chain that coprecipitated with β_2m . Thus, each of the HLA-E, -F and -G genes encodes an HLA class I heavy chain that associates with β_2m ; however, only the HLA-G gene encodes a class I protein that gets to the cell surface of the B-LCL.

RNAase protection has been used to examine the expression of HLA-E, -F and -G transcripts of different human cell lines and tissues. The pattern of expression of HLA-E and HLA-F transcripts is, for the most part, very similar to that of HLA-A, -B and -C genes. HLA-E and HLA-F transcripts were detectable in RNA from almost all cell lines and tissues examined. The amount of HLA-E and HLA-F transcripts detected varied between the different cell lines and tissue types. Higher levels of HLA-E and HLA-F transcripts were found in lymphoid cells as compared to nonlymphoid cells. Moreover, within

lymphoid tissues, mature T cell lines expressed higher levels than immature T cell lines. The highest level of HLA-E transcript was detected in resting T lymphocytes, but this was decreased dramatically upon activation by PHA. HLA-E and HLA-F transcripts were also detectable in RNA from nonlymphoid tissues, and liver had a very low amount of these mRNAs. There are two HLA-E transcripts, 1.95 kb and 3.3 kb, differing only in the extent of the 3' untranslated region. Whereas the 1.95 kb transcript uses one of the first two polyadenylation signals, the 3.3 kb mRNA terminates after a distant polyadenylation signal. The ratio of the two mRNA species is dependent on cell type and the differentially regulated two HLA-E mRNA species might be important in the control of its function.

The HLA-G gene is unique among HLA class I genes identified so far in that its expression is highly restricted. The HLA-G transcript has been found only in extraembryonic tissues during gestation, eye tissue and at a very low level in fetal thymus. Furthermore, the level of HLA-G transcript in placenta and extravillous membrane changes with time of gestation. At the 10th week, HLA-G transcript was found in RNA from placenta and not in RNA from extravillous membrane. At the 21st week of gestation, both placental and extravillous membrane RNA contained HLA-G transcript. At term, the HLA-G transcript was detectable only in RNA from extravillous membrane.

An interesting point concerns the cellular sites of HLA-G expression with the placenta and extravillous membrane. HLA-G transcript has been detected in chorionic cytotrophoblasts at term. Both HLA-G transcript and protein were detected in the first trimester villous cytotrophoblasts, and were greatly reduced in the third trimester villous cytotrophoblasts. These data suggest that the fetal cytotrophoblasts are the cellular sites of HLA-G expression.

HLA class I gene polymorphism and functions

An important aspect of the HLA-A -B, and -C genes is their high level of polymorphism. Currently, over 80 alleles at the HLA-A locus, 185 at the HLA-B locus, and 42 at the HLA-C locus have been defined. Comparison of sequences from a single locus shows the class I heavy chains are divided into a variable part comprising the $\alpha 1$ and $\alpha 2$ domains and a relatively conserved part consisting of $\alpha 3$, the transmembrane, and the cytoplasmic domains. The $\alpha 1$ and $\alpha 2$ domains are known to bind diverse antigen peptides and form the site of interaction with variable T cell receptors. There are 20 amino acid positions with

high variability, all in the $\alpha 1$ and $\alpha 2$ domains, which have been defined from a comparison of 39 HLA-A, -B and -C sequences. From the HLA-A2 structure, 47 residues were hypothesized to make contact with bound peptide, or to interact with the T cell receptor. Of the 20 residues of high variability, 19 residues are included in this group. In contrast, HLA-E, -F and -G genes show relatively little polymorphism.

The HLA-A, -B and -C antigens are the major antigens recognized by the host during tissue graft rejection. Cytotoxic T lymphocytes recognize viral antigens only in the context of a class I antigen. T lymphocytes elicited by such an exposure are restricted in their killing to the cells which bear the same class I antigens as were present on the sensitizing cells.

It has been postulated that HLA-C is a declining class I gene, since HLA-C has fewer alleles than HLA-A and HLA-B, differing by smaller numbers of substitutions which are frequently at positions not directly involved in contacting the bound peptide and the T cell receptor. In addition, there is much less HLA-C antigen than HLA-A and HLA-B antigen on the cell surface. However, HLA-C molecules are capable of antigen presentation, as demonstrated by experiments with transgenic mice. Whether there are sufficient HLA-C restricted T cells for this to happen with any frequency in the human immune response is a matter for question. All this evidence supports the idea that HLA-C contributes little to human immunity.

So far, no function has been assigned to HLA-E, -F and -G class I products, although it has been demonstrated that HLA-G is able to present peptides in a similar fashion to the classical class I molecules. Restriction of HLA-G expression to fetal extraembryonic tissue implies that HLA-G subserves a function critical to this tissue. Within the extraembryonic tissues, fetal cytotrophoblasts are exposed to the maternal decidua. It has been suggested that fetal trophoblasts function to shield the fetus from recognition by the maternal immune system. Clearly, the lack of HLA-A, -B and -C expression by these cells is consistent with such a function. Expression of the nonpolymorphic class I gene HLA-G should not result in fetal rejection by the maternal immune system, assuming the maternal immune system does not recognize HLA-G as foreign. It has been proposed that HLA-G may function to directly protect fetal cytotrophoblasts by activation of maternal suppressor cells or blockage of maternal cytotoxic cells.

HLA-G expression by fetal cytotrophoblasts may also function to enable the maternal immune system to survey these fetal cells, much as it does other maternal somatic cells. An immune surveillance

capability seems warranted since fetal trophoblast cells play a crucial role in the development of the embryo. HLA-G on the surface of fetal cytotrophoblasts could afford a mechanism by which an antigen is presented to the maternal immune system, for example, in case of a viral infection, while keeping the fetal cells from being seen as foreign by the maternal immune system. HLA-G may have non-immunologic roles in modulating receptivity to soluble growth and differentiation molecules or it may be required for interplay with decidual cells.

Conclusions

Human histocompatibility class I molecules consist of a MHC-encoded heavy chain and an invariant β_2m . In the HLA gene complex, there are 17–20 class I heavy chain genes including various pseudogenes and gene fragments. Only six genes (HLA-A, -B, -C, -E, -F and -G) are known to encode β_2m -associated molecules. HLA-A, -B and -C molecules are present on virtually all nucleated cells. HLA-E and -F transcripts have been detected on almost all cell lines and tissues examined. In contrast, HLA-G expression is restricted to extraembryonic tissues during gestation, eye tissue and at a very low level in fetal thymus. HLA-A, -B and -C genes are highly polymorphic and encode antigen-presenting molecules. On the other hand, HLA-E, -F and -G genes show very little polymorphism and their functions are unknown.

HLA CLASS II

Eric O Long, Laboratory of Immunogenetics, NIAID National Institutes of Health, Maryland, USA

HLA class II molecules are absolutely essential in the generation of a proper immune response. They function to display peptides at the surface of antigen-presenting cells for recognition by CD4⁺ T cells. HLA class II molecules consist of polymorphic α/β chain heterodimers encoded in genes of the human major histocompatibility complex (MHC). The first indication for the existence of a genetic region, distinct from HLA class I, that was important for the immune response came in 1967 when Bach and Amos observed the proliferation of mixed lymphocytes derived from HLA class I-matched donors. Genetic studies, reported in 1971 by Yunis and Amos, established what is now called HLA-D as the region controlling mixed lymphocyte responses. Thus, it is because of the high degree of allelic polymorphism in HLA class II genes that they were discovered, long before their structure or function were known. This polymorphism also led to a serological characterization of these molecules with alloantisera, first for HLA-DR, and later for HLA-DQ. The class II allelic specificities, defined either by cellular typing (Dw specificities) or serologically (DR and DQ specificities), correlated well with graft rejection between unmatched individuals. A new allelic series, designated HLA-DP, was defined by primed lymphocyte typing. Biochemical studies demonstrated that DR, DQ, and DP class II molecules consisted of distinct α/β heterodimers. The molecular cloning of class II genes in 1982 opened a new era. Recombinant DNA technology has made it possible to determine the sequence of most class II alleles. Molecular typing procedures are now in use to define allelic specificities with greater precision than cellular or serological techniques. Furthermore, expression of class II molecules after DNA-mediated gene transfer into cell lines or mice has become a powerful tool to study their function.

Structure and diversity

HLA class II genes map to position 6p21 on the short arm of chromosome 6, in the D region of the human MHC. The molecular description of the D region was derived from a combination of genetic studies, of *in vitro*-derived deletion mutants, and of mapping with cosmid DNA clones and pulsed-field gel electrophoresis of large DNA fragments (Figure 1). The D region is divided in three major functional subregions encoding the DR, DQ and DP molecules. A functional pair of α and β genes is present in each subregion.

In addition, the DP and DQ subregions contain a pair of α and β nonfunctional genes. The DR subregion is more complex. It contains a single α gene and several β genes, the number of which varies among different HLA haplotypes. DR1 and DR8 haplotypes express a single functional β gene, whereas most

Figure 1 Molecular map and gene products of the HLA-D region. The orientation is: centromere to the left, class I genes and telomere to the right. The genes, grouped within subregions DP, DQ and DR, are represented as boxes and are not drawn to scale. Genes encoding α chains and β chains are designated A and B respectively. The DR subregion usually only contains two expressed B genes: B1 and one of either B3, B4 or B5. The nucleotide sequences of A and B genes within a subregion are more related than they are to those of genes in other subregions.

other DR haplotypes express two isotypic β genes, the product of which pairs with the same α chain. One DR molecule shows a higher degree of allelic polymorphism, and is encoded by the B1 gene (or B5 for the DR2 haplotype). A second DR molecule, with less allelic polymorphism and strong linkage disequilibrium with the first, is encoded by gene B3 or B4 (or B1 for DR2 haplotype). Gene B2 is nonfunctional.

Two additional expressed genes for which no product or function has been assigned yet are DNA and DOB. They are located between the DP and DQ subregions. The fact that they encode a translatable class II α or β chain, respectively, and their evolutionary conservation suggest that they serve some function.

The α and β chains are transmembrane glycoproteins with relative molecular masses of 35 000 and 29 000 respectively. After their cotranslational translocation into the endoplasmic reticulum, they assemble into a very stable noncovalent trimer with the invariant chain, a nonpolymorphic protein with a relative mass of 33 000. Prior to surface expression of class II molecules, the invariant chain is removed by proteolytic cleavages in an acidic intracellular compartment.

The allelic diversity of class II molecules is much greater than their isotypic diversity. Nucleotide sequencing of class II genes from different individuals revealed a greater heterogeneity than had been detected by serological or cellular typing. According to the 1996 WHO Nomenclature Committee for Factors of the HLA System, there are 215 recognized sequences for the DRB genes, 18 for DQA, 31 for DQB, 10 for DPA and 77 for DPB genes. The coding region for the extracellular portion of the DR α chain is nonpolymorphic.

The DR specificities defined by serology describe an allelic series that has been rather stable through evolution. Certain existing alleles have clearly preceded speciation, and closely related sequences can be found in nonhuman primates. A practical result of this genetic stability in DR alleles is that most DR specificities can be determined based on restriction fragment length polymorphism (RFLP) of DNA. However, many DR specificities can be subdivided by cellular typing (the Dw series). These 'splits' of DR specificities are due to small sequence alterations, affecting mostly the third variable region of the β chain, which is critical in specific T cell contacts. This variability must have evolved more recently than the DR allelic series; it has not been detected by RFLP.

A large number of diseases with an autoimmune component occur at elevated frequencies in individuals with certain class II specificities. The precise definition of class II specificities and of their underlying amino acid sequences has led to improved disease

associations. An important goal in understanding the basis for autoimmune disease is to identify the particular class II molecule, and the particular self peptide, that may be involved in triggering autoimmune T cells.

Function

The main function of HLA class II molecules is to present peptides to CD4⁺ T lymphocytes. By analogy with the mouse immune system, it is likely that this presentation occurs already in the thymus, where maturing T cells undergo both negative and positive selection. Mature peripheral CD4⁺ T cells are stimulated by antigen-presenting cells (APCs) when the proper combination of antigenic peptide and class II molecule is displayed at the surface of the APC. Several types of cells express class II molecules and can serve as APCs: dendritic cells, monocytes, macrophages and B cells. Class II expression on APCs is regulated by cytokines; it is enhanced in monocytes by interferon γ (IFN γ) and in B cells by interleukin 4 (IL-4). Cytokines may also induce class II expression in a variety of cells that are otherwise class II negative, such as fibroblasts. These cells can then acquire the ability to present antigen to CD4⁺ T cells.

Antigenic proteins are generally not recognized as such by T cells, but have to be processed into a form that can bind to MHC molecules. In general, antigen processing for presentation by class II molecules involves antigen uptake into an endocytic compartment where processed peptides encounter either newly synthesized class II molecules on their way to the cell surface, or surface class II molecules that are internalized and recycled. The biosynthetic route of class II molecules is distinct from that of class I molecules, in that class II molecules are targeted to a post-Golgi compartment, accessible to endocytosed material, where they are retained for a few hours. This specialized transport to the cell surface is presumably what makes class II molecules so efficient in the presentation of exogenous antigen. However, class II molecules are not limited to the presentation of exogenous antigens, because, at least in some cases, class II molecules are able to present endogenously processed antigen.

A failure to mount an immune response to a particular antigen can be caused by 1) an inability of the host's APCs to process the antigen, 2) the lack of a class II molecule to which the foreign peptides can bind, or 3) the absence in the T cell repertoire of a T cell receptor (TCR) with the proper specificity. To avoid the second possibility, and because the isotypic diversity in class II molecules is small, each class II

molecule must be able to bind many different peptide sequences. Although this is the case, some specificity in peptide binding can be defined. Only one or two crucial amino acids within a peptide account for the binding specificity. This explains why many different peptides, apparently unrelated in sequence, bind to the same class II molecule.

The structure of the peptide-binding site on class II molecules consists of a binding groove or cleft which, unlike the class I binding groove, is open at both ends, permitting peptides of 12–24 residues to be bound. Polymorphic amino acid residues that define the specificity in peptide binding lie on the floor of the binding groove, formed by the parallel β strands at the amino-terminal ends of the $\alpha 1$ and the $\beta 1$ domains, and on the inner face of the α helices that span the top of class II molecules. Residues on the α helices facing up have been identified that are critical for T cell recognition, in particular in the third variable region of the DR $\beta 1$ domain.

A particular class of antigens, termed 'superantigens', bind to class II molecules and elicit the stimulation of a large proportion of T cells, according to the V β chain of their TCR. Superantigens include a number of bacterial toxins produced by staphylococci, streptococci and mycoplasma. They do not require processing for T cell stimulation and display a hierarchy of affinities for different class II molecules. They apparently make external contacts with class II molecules and with the V β chain of TCRs, away from the sites involved in peptide binding and recognition.

Class II molecules may well carry out other functions besides presentation of antigens to T cells. Signaling via class II molecules occurs and could play a role in the control of cell differentiation during hematopoiesis. Surface expression of class II molecules is induced on activated human T cells; no role has been attributed yet to this induction. The expression of DR, DQ and DP molecules is not always coordinated in hematopoietic cells. The possibility that the multiplicity in class II isotypes serves specific functions, other than the expansion of potential immune responses to diverse antigens, must be considered.

HLA CLASS III REGION

Caroline M Milner, Begoña Aguado and R Duncan Campbell, MRC Immunochemistry Unit, Department of Biochemistry, University of Oxford, Oxford, UK

The human major histocompatibility complex (MHC) spans approximately 4 Mbp on the chromosome band 6p21.3 and is divided into three regions. The class I and II regions contain the classical MHC genes, which encode cell surface glycoproteins involved in the presentation of antigenic peptides to T cells. These are interspersed with a large number of other genes, some of which encode proteins involved in antigen processing. The 1100 kb segment of DNA that separates the class I and II regions is generally termed the class III region and contains at least 63 genes which encode proteins of diverse function (Figure 1).

The class I and II regions of the MHC are typified by a high level of gene duplication and extensive polymorphism. These features are less apparent in the class III region, but this does contain several clusters of related genes, for example, those encoding:

four components of complement; three members of the 70 kDa heat shock protein (hsp 70) family; and the cytokines tumor necrosis factor (TNF), lymphotoxin α (LT α) and LT β . The MHC class I chain-related (MIC) gene family has two members (MICA and MICB) between HLA-B and BAT1 and a further three related gene fragments within the class I region. The PERB (Perth MHC β -block) sequences also include class I-like pseudogenes and gene fragments. Most of the other genes in the class III region are single copy, but some have related genes elsewhere in the genome.

Encoded proteins

Genomic or cDNA fragments corresponding to most of the class III region genes have been cloned and

Figure 1 Molecular map of the human MHC class III region. The positions of genes, pseudogenes and gene fragments are indicated by filled boxes, as indicated in the key, except for the YA and YB genes, which are indicated by open boxes. The approximate region within which the cyclophilin pseudogene (PIIP) is known to lie is marked by a horizontal black box. The directions of transcription of genes, where known, are shown by horizontal arrows.

sequenced. Those that encode proteins with known or putative functions are discussed here and, together with the others, are listed in Table 1.

NOTCH4, the human counterpart of mouse mammary tumor gene, *int-3*, encodes a member of the Notch family of transmembrane proteins. Notch was first identified as a *Drosophila* neurogenic locus required for cell lineage determination in embryogenesis. However, Notch and its homologs are widely expressed during embryonic and adult development and participate in cell-cell interactions, mediating a variety of regulatory events.

The G17 gene encodes PBX2, a homeodomain-containing protein related to PBX1. The latter is involved in acute pre-B cell leukemias. While most of the *Drosophila* homeodomain-containing proteins have been implicated in developmental processes, the functions of the majority of the non-*Drosophila* proteins remain unknown. However, it has been suggested that these proteins function as sequence-specific DNA-binding proteins that play an important role in transcriptional regulation.

RAGE (a receptor for advanced glycosylation end-products of proteins) is a member of the immunoglobulin superfamily of cell surface molecules. AGEs are nonenzymatically glycosylated proteins that accumulate in vascular tissue as a result of aging, and at an accelerated rate in diabetes, due to the prolonged exposure of proteins to aldoses such as glucose and ribose. RAGE mediates monocyte migration and activation in response to AGEs, but other binding sites may also contribute to this. Binding of AGE to endothelial RAGE induces cellular oxidative stress, resulting in increased vascular permeability and activation of NF- κ B. RAGE may have other functions in addition to the binding and subsequent uptake of AGEs.

The G13 protein contains a leucine zipper consensus sequence preceded by two basic clusters, separated by an alanine spacer (bZip domain). This domain is conserved in many transcription factors including the cyclic AMP response element-binding protein (CREB) family, which comprises proteins that show sequence-specific binding to DNA (via a region rich in basic amino acids) and use dimerization to control function (via a leucine zipper domain).

The XB (TN-X) and XA genes overlap the 3' ends of the P450c21B/A genes by 481 bp, respectively, and are transcribed in the opposite orientation to the C4, P450c21 and Y genes. The protein encoded by XB has been termed tenascin-X (TN-X), due to its structural similarity to tenascin (TN-C). The tenascins are a family of extracellular matrix proteins, the functions of which are unclear, but TN-C can facilitate cell movement by counteracting the cell adhesion

and spreading activity of fibronectin *in vitro*, and may also be important in embryogenesis. A short form of XB (XB-S) is transcribed from a promoter within intron 26 of TN-X. The nucleotide sequence of the XA gene is more than 99% identical to XB-S, but XA contains premature stop codons, so it is unlikely to encode a protein.

The P450c21B and P450c21A genes share 97% overall nucleotide sequence identity. P450c21B encodes the adrenal enzyme steroid 21-hydroxylase, which is involved in the conversion of progesterone and 17-hydroxyprogesterone to 11-deoxycorticosterone and 11-deoxycortisol, the intermediate steps in mineralocorticoid and glucocorticoid biosynthesis, respectively. P450c21A contains deleterious mutations and so cannot encode a functional protein.

The YB and YA genes utilize the p450c21B/A gene promoters, and are transcribed in the same orientation as the latter, but use a different array of exons and introns. It has not been established whether the YA/YB transcripts are translated into protein.

The complement system is the principal effector mechanism of humoral immunity and consists of at least 24 serum and 11 membrane-bound proteins. Its activation via the classical or alternative pathway leads to cell lysis, opsonization, clearance of immune complexes, regulation of B cell responses, and the generation of peptides that have potent anaphylactic and chemotactic activities. C2 and C4 are major effector proteins of the classical pathway, which is activated by the binding of C1 to immunoglobulin G (IgG) or IgM, complexed with antigen, or following the interaction of mannan-binding protein with carbohydrate ligands on the surfaces of bacteria or viruses. Factor B (Bf) is a component of the alternative pathway, which is activated by a diverse set of substances including components of yeast and bacterial cell walls and is usually antibody-independent. C4A and C4B differ by only four amino acids, but this results in a profound difference in their covalent binding activities. Both isotypes of C4 are highly polymorphic, whilst C2 and Factor B show more limited polymorphism.

Genomic sequence analysis of G11 has shown that its 3' end was involved in the duplication event giving rise to the two C4/P450c21/X/Y gene clusters. The predicted protein products of G11 contain bipartite nuclear localization signals and partial sequence similarity with the tyrosine kinase-transforming protein from the fujinami sarcoma virus. This, and the presence of potential sites for phosphorylation at Ser/Thr and Tyr residues, may suggest that G11 has a novel kinase-like activity.

The G11a (SK12W) protein contains an RNA helicase domain and a leucine zipper motif, and shows

^aTissue distribution is based on published data. The names of tissues and primary cells are given in full, except for macrophages (M ϕ). Single letter codes indicate tissue culture cell lines corresponding to: epithelial cells (E); fibroblasts (F); hepatocytes (H); lymphoid cells (i.e. T and B cells) (L); myeloid cells (including some or all of erythrocytes, granulocytes, monocytes, macrophages and promyelocytes) (M); and T cells (T). *Indicates that an mRNA is expressed specifically in the cell line(s) or tissue(s) shown. Where an mRNA is expressed at particularly high levels in a cell line or tissue this is shown in bold text.

extensive similarity to the yeast antiviral protein Ski2p and the human protein KIAA0052. Helicases are essential enzymes, being required to unwind DNA during replication, repair, recombination and transcription, and RNA during splicing and translation. Many RNA viruses do not contain a poly(A) tail and/or this is not capped. Ski2p exerts its antiviral action by translational inhibition of poly(A)⁺ RNA.

The C-terminal region of G9a (which binds zinc *in vitro*) shows ~33% amino acid sequence identity with the C-terminal regions of *Drosophila* trithorax and its human homolog HRX, both of which are involved in the regulation of transcription during development. G9a also contains six contiguous cop-

ies of the 33 amino acid ANK repeat. This repeat is thought to mediate protein-protein interactions and is found in proteins of diverse function, including *Drosophila* Notch and NF- κ B.

The G9 gene encodes a protein with 28% sequence identity to the *Salmonella typhimurium* sialidase and recombinant G9 protein has sialidase activity with an acidic pH optimum, characteristic of a lysosomal enzyme. Sialidases are important in modulating cellular functions by regulating the sialic acid content of glycoproteins and glycolipids. The *Neu1* locus, which encodes liver sialidase activity and regulates the sialic acid content of several lysosomal enzymes, has been mapped to the murine class III region. Neu1

activity is upregulated in activated T cells with a concomitant reduction in cell surface sialic acid content. The latter is probably due to hyposialylation of cell surface proteins and is a requirement for T cell responsiveness to alloreactive B cells.

The hsp70s are a highly conserved family of proteins, found in all species, and are expressed both constitutively and in response to a variety of stress factors. HSP70-1 and -2 both encode the major heat-inducible HSP70 and their expression is upregulated in response to heat shock. However, sequence variation in their 5'- and 3'-untranslated regions may result in differential expression in response to other stress factors, such as oxidative injury and inflammation. HSP70 is normally expressed at low levels in the cytosol, but following heat-shock it is found predominantly in the nucleus and nucleoli where it aids cell recovery by catalyzing the refolding and disaggregation of damaged and denatured proteins. HSP70-HOM encodes a protein 90% identical to HSP70-1/-2, but its expression is not heat-inducible. All hsp70s can bind unfolded proteins and peptides and act as chaperones in the synthesis, folding, assembly, translocation and degradation of proteins during normal cellular processes and following stress. Sequence variation between the ~18 kDa peptide-binding domains of the hsp70s may be reflected in functional diversity. There is evidence that HSP70 can bind to immunomodulatory peptides and act as an immunophilin. Cytosolic hsp70s have also been implicated in the transport of peptides during antigen processing in tumor cells.

The G7a protein shows 48.3% identity with the valyl-tRNA synthetase (Trs^{Val}) of *Saccharomyces cerevisiae*, and functional studies on recombinant G7a have confirmed that it is the human Trs^{Val}. G7a has a unique N-terminal region which may be involved in the interaction of human Trs^{Val} with elongation factor 1H.

The G5a gene encodes the casein kinase II (cII) β subunit. CkII is a highly conserved serine protein kinase, consisting of a heterotetramer of α and α' catalytic subunits and two regulatory β subunits. The β subunit is required for high activity phosphorylation of the α subunit. CkII has been linked to the regulation of cell growth and metabolism as many of its substrates (such as insulin, epidermal growth factor and a variety of cellular and viral oncoproteins) play key roles in cell growth.

The G1 protein contains two potential 'EF-hand'-type calcium-binding domains, similar to those found in calmodulin. The restricted expression pattern of G1 suggests a possible role in an intracellular signaling pathway during T cell activation or macrophage stimulation when intracellular calcium levels rise.

The cytokines TNF, LT α and LT β belong to the TNF ligand superfamily. TNF occurs as membrane bound and secreted homotrimers, both of which are biologically active. LT α also forms secreted homotrimers, but can be retained at the cell surface as heterotrimers with LT β . TNF has antitumor activity and exhibits numerous inflammatory and immunomodulatory activities. LT α shows similar activity *in vitro*, but is often less potent than TNF. Recent studies suggest a unique role for secreted LT α in the generation of germinal centers, and membrane-bound LT α has been implicated in the development of the spleen, lymph nodes and Peyer's patches.

The ikbl protein contains two copies of the 33 amino acid ANK repeat followed by a third poorly conserved ANK repeat and a short region rich in acidic amino acids. A similar pattern of sequence elements is found in the I κ B family of transcription factor inhibitors. The Rel family of transcription factors, which includes NF- κ B, regulates the expression of a wide variety of genes including cytokines, cytokine receptors, and stress proteins. In unstimulated cells these transcription factors are maintained in the cytosol due to their association with inhibitors belonging to the I κ B family. Stimulation of cells by agents such as phorbol myristate acetate (PMA), IL-1 β , TNF and lipopolysaccharide (LPS) results in the phosphorylation and subsequent degradation of the I κ B protein, allowing translocation of the free Rel proteins to the nucleus.

The BAT1 protein, which is localized in the nucleus, shows significant sequence similarity to the DEAD-box protein family of ATP-dependent RNA helicases. RNA helicases participate in diverse cellular functions such as initiation of translation, RNA splicing, ribosome assembly, spermatogenesis, oogenesis and cell growth and division.

The MICA and MICB proteins share 83% identity and have the same domain structure as the class I heavy chains. However, they are highly divergent from the classical and nonclassical class I genes and differ in their patterns of expression. The MIC proteins lack the residues of the class I heavy chains involved in CD8 binding. MICA does not associate with β_2 microglobulin and is stable in the absence of class I peptide ligands. MICA is mainly expressed in the gastrointestinal epithelium and is upregulated in response to cell stress, suggesting a possible role in the gut mucosal immune system.

Disease association

The MHC is associated with a large number of diseases, many of which are autoimmune in nature. Allelic variants of the class II, and to a lesser extent

class I, molecules account for some of these associations, but there is evidence to suggest that the class III region may also contain disease susceptibility genes. For instance: the central segment of the class III region, containing the RD, G11 and G11a genes, has been implicated in IgA deficiency and common variable immunodeficiency (CVID); Orch-1, a susceptibility gene for orchitis, an autoimmune disease of the testes, has been mapped to the region between G7 and HSP70-HOM in the mouse; and the region between the TNF/LT gene cluster and HLA-B is thought to be important in susceptibility to type I diabetes and myasthenia gravis.

In addition, the functions of some proteins suggest possible roles in disease. For example, RAGE could contribute to diabetic complications by modulating cellular function following interaction with AGEs and expression of RAGE is upregulated in the vasculature in a range of vasculopathies, in atherosclerotic vascular lesions and in immune inflammation vasculitides. Casein kinase II activity appears to be upregulated in the neurofibrillary tangles in the brains of Alzheimer's Disease (AD) patients and associations of HLA-A2 and -DR3 with AD have been reported.

Increased expression of hsp70s has been observed in autoimmune diseases such as scleroderma and systemic lupus erythematosus (SLE), but it is not clear whether this is a contributory factor or a consequence of disease. However, exposure of keratinocytes to ultraviolet light results in accumulation of HSP70 in the nucleoli and a concomitant increase in binding sites for autoantibodies to nuclear antigens which are a feature of erythematosus lesions. Some allelic variation has been found in the MHC-linked hsp70 genes, but numerous studies have failed to show a direct contribution of any of the variants to a particular autoimmune disease.

Complete deficiency of C4 is rare and is correlated with severe immune complex disease, whereas partial deficiency of C4 is more common and is thought to be associated with an increased susceptibility to SLE, scleroderma and primary biliary cirrhosis. Deficiency of P450c21B is the most frequent cause (95%) of congenital adrenal hyperplasia (CAH), which is characterized by accumulation of 17-hydroxyprogesterone and production of excess androgen. Classical CAH occurs as the milder simple virilizing form and the more severe, and life-threatening, salt-wasting form. In addition there is a nonclassical late-onset form where individuals remain asymptomatic or develop the symptom of an excess of androgens in childhood or at puberty. Deficiency in sialidase activity can result in sialidosis, a lysosomal storage disorder characterised by various developmental and neurological abnormalities. Mice carrying a *Neu1*

allele that confers only some 17% of normal liver sialidase activity are small at birth, and show a high incidence of amyloidosis and low lymphocyte response to the mitogen phytohemagglutinin.

Conclusion

Detailed characterization of the MHC class III region has so far led to the localization of over 60 transcriptional units, with sufficient intergenic gaps for this number to increase significantly. Many of the genes are very closely packed: for example G11 and C4 are separated by 611bp; RAGE and PBX2 by approximately 500 bp; and C2 and factor B by just 421 bp. The 120 kb segment of DNA containing the duplicated C4/P450c21/X/Y gene cluster is one of the most complex in the human genome and contains overlapping genes and genes within genes. An understanding of the functions of all the proteins encoded in the class III region will be very valuable in identifying those genes that may be involved in disease susceptibility.

HOOKWORM DISEASE

Jerzy M Behnke, Department of Life Science, University of Nottingham, Nottingham, UK

In its widest context, the term 'hookworm disease' may be applied to any of the pathologic consequences resulting from infection by hookworms, i.e. nematode parasites from the family Ancylostomidae. More specifically, the term is used in a restricted sense in reference to hypochromic, microcytic, iron-deficiency anemia, the principal manifestation of pathology in humans. Since the disease is entirely dependent on the presence of adult hookworms in the small intestine and the blood loss resulting from their feeding activities, resistance to hookworm disease is reliant on host-protective immune responses against the parasites.

Characteristics of the organisms and their antigens

Three species of hookworms have the capacity to mature in humans and to cause disease; others parasitize domestic animals and cause similar diseases. Each has its own characteristic features, with differences in important aspects of their biology, including the possession of species-specific antigens and the induction of species-specific pathology. Immunity in hookworm disease must therefore be considered against this background of heterogeneity in the causative organisms and associated immune responses by the host.

Two species, *Ancylostoma duodenale* and *Necator americanus*, are essentially anthrophilic and in nature transmission is maintained only by the reser-

voir of mature egg-laying parasites within infected people. The third species, *A. ceylanicum*, is primarily a parasite of carnivores but develops to maturity in humans, as evidenced among Dutch soldiers returning from active service in West New Guinea and by volunteer experiments among laboratory personnel. There are recent reports from Australia of *A. caninum* causing patent infections in humans, but this species is not generally regarded as being capable of developing fully in the human host. The pertinent details of these species and others are summarized in Table 1.

All hookworms have a characteristic life cycle which begins with the liberation of parasite eggs in host feces. These take a few days to hatch and the larvae then develop through three free-living larval stages, each separated by a molt, into the infective third stage (L3). The species differ in the routes used for entering a potential host. *N. americanus* is an obligatory skin penetrator and can only mature after a larval migration phase; L3 larvae stay at the skin site for about 2 days before migrating through the blood stream to the lungs, where further development lasting about 1 week takes place. The advanced L3 larvae then migrate up the trachea and are swallowed, passing through the esophagus to the stomach and intestine. During this migration the worms molt to the fourth stage. It is now generally accepted that *N. americanus* cannot establish directly in the intestine upon ingestion of third-stage infective larvae, however, during oral infection some larvae may pen-

Table 1 Hookworm species affecting humans and domestic animals

<i>Necator americanus</i>	Both virtually restricted to humans
<i>Ancylostoma duodenale</i>	
<i>Ancylostoma ceylanicum</i>	Closely related, both are parasites of carnivores, particularly dogs. However, <i>A. ceylanicum</i> can cause patent infections in humans whereas <i>A. braziliense</i> is commonly associated with cutaneous larva migrans
<i>Ancylostoma braziliense</i>	
<i>Ancylostoma caninum</i>	These species are also closely related to each other. <i>A. caninum</i> can cause cutaneous larva migrans but does not generally mature in humans, although some reports from Australia have identified adult worms in human subjects
<i>Ancylostoma tubaeforme</i>	

In addition to the parasites listed above, a variety of other members of the family Ancylostomatidae affect domestic animals. Among the best known are *Gaigeria pachyscelis* (sheep), *Bunostomum trigonocephalu* (sheep), *B. phlebotomum* (cattle) and *Uncinaria stenocephala* (dogs). To some degree all have the capacity to aggravate human skin during attempts at penetration.

erate the buccal mucosa and travel to the lungs to complete development in the normal way.

In contrast, members of the genus *Ancylostoma* can readily establish in the intestine following oral infection, without the need for a tissue migration. In addition *Ancylostoma* spp. have the capacity to migrate to the intestine after skin penetration, but unlike *Necator*, *Ancylostoma* do not develop until they arrive in the small intestine. In comparative trials *A. duodenale* established more successfully after oral compared with percutaneous infection, the reverse being true for *Necator*.

The L4 and adult stages of all hookworms live in the small intestine, although in heavier infections parasites may be encountered in the large intestine. *A. duodenale* is considered to be more pathogenic than *N. americanus* and this is probably related to its deeper penetration of the mucosa during feeding.

In recent years it has been recognized that *A. duodenale*, in common with most other *Ancylostoma* spp. has the capacity to undergo arrested development. This has important implications for the epidemiology of the disease and also for consideration of immunological intervention in controlling hookworm disease. Essentially, most of the larvae acquired in the transmission season in hot climates (invariably the rainy and postmonsoon season), instead of immediately completing development, follow a protracted course of development and begin to produce eggs only a few weeks before the anticipated onset of the following rainy season. The parasites thus conserve resources (which would otherwise be spent in unsuccessful reproduction) for the period when transmission is most likely to succeed. *Ancylostoma* spp. probably evolved initially as parasites of carnivores and only secondarily adapted to primates. Indeed it has been suggested that *A. duodenale* may have evolved from *A. caninum*, as a consequence of the long association between humans and dogs. Carnivore parasites profit from arrested development in being able to utilize paratenic hosts such as rodents. The larvae migrate to muscle sites in abnormal hosts

and can survive in an arrested form for over 12 months, generating an opportunity for transmission to the definitive host through the food chain. *A. duodenale* appears to exploit this capacity to maximize transmission efficiency during the limited period when conditions are appropriate. In fact oral infection with *A. duodenale* via meat-borne larvae has been demonstrated experimentally. As far as is known, *Necator* cannot undergo arrested development.

One consequence of the differences in the biology of hookworms outlined above is that the quality, intensity and duration of antigenic stimulation for the host is dependent on the species of hookworm involved. In common with other nematodes, hookworms produce a variety of excretory-secretory (ES) molecules, some of which have important functional roles for the parasites and the majority of which are immunogenic to some extent. Comparisons between the species have again identified key differences but to date only a few defined ES antigens have been studied in detail.

Acetylcholinesterase is secreted by *Necator americanus* and other species of intestinal nematodes and is believed to interfere locally with the muscular activity of the intestinal walls, conceivably providing a better environment for the worms. The enzyme may also play a role in downregulating local mucus secretion and leukocyte activation. *A. duodenale* secretes only 12% of the quantity released by *N. americanus* and *A. tubaeformae* and *A. ceylanicum* produce minimal quantities. *N. americanus* secretes antioxidant enzymes which reduce the concentration of free radicals in the vicinity of the parasite. High concentrations of superoxide dismutase, glutathione-S-transferase and catalase activity have been detected.

Adult hookworms secrete proteases, among which hyaluronidase and anticoagulase properties have been identified. The anticlotting activities include prevention of platelet aggregation and blockage of factor Xa, the latter caused by *A. caninum* anti-

coagulant peptide (AcAP). This species also secretes NIF (neutrophil inhibitory factor, a 41 kDa glycoprotein) which blocks CD11b/CD18 (Mac-1) neutrophil-dependent function, including release of oxidative mediators and adherence to the capillary endothelium. A metalloprotease (36–37 kDa), with anticoagulant and elastolytic properties, which is partially protective when used in an experimental vaccine has also been isolated from *A. caninum*. *N. americanus* secretes several proteases which have a range of pH optima, varying molecular weights and which show a number of biochemical properties, distinguishing them from the enzymes produced by *Ancylostoma* spp. Among the properties of these enzymes is the capacity to digest IgA, the main immunoglobulin isotype associated with the mucosa of the intestine. In general, the proteases secreted by *Ancylostoma* spp. are more similar to each other than to those produced by *Necator*, but some degree of serological cross-reactivity implies that common epitopes are expressed by the proteases of the two genera. In view of their important functional roles in parasite biology, inactivation of ES proteases through vaccination may offer a potential route to future immunoprophylaxis.

The molecular components of the hookworm cuticle have also been studied. The surface molecules are only loosely attached and overlie more important structural elements which are hidden from the host's immune system. It has been proposed that a sustained antibody response to the surface components may result in their removal. Subsequent exposure of the now unprotected deeper elements to a second wave attack of specific antibody, may result in lethal damage to the worms.

Hookworms are highly complex organisms and there is still much to be learned about the possible targets of immune attack. Sensory organs of hookworms have been relatively neglected and yet impairment of the parasite's sensory systems could have severe consequences for parasite viability and may prove a fruitful path to the development of effective vaccines.

Immune responses of the host

Epidemiology

People living in endemic environments become exposed to hookworm larvae from early childhood and consequently worm burdens build up throughout life or, in some communities, until a point of relative stability is achieved in late teenage years. The parasites are extremely long-lived. *Necator* has been shown to live up to 18 years in an experimentally infected volunteer. In the field, parasite longevity is

probably shorter and a turnover of worms must occur sooner or later, particularly in those communities which show stability of worm burdens in the 20–50 year age group. However, there are significant differences in epidemiology between the major species affecting humans, which are not always apparent in the field because mixed species infections are common. Where single-species infections have been studied, *Necator* causes stable infection intensities throughout the year whereas *A. duodenale* oscillates in a clear annual cycle with peak parasite burdens just after the transmission season.

The principal feature of hookworm infections in endemic regions is the absence of declining intensities of parasite burdens in older age groups which have experienced continuous exposure to infective larvae throughout life. If immune mechanisms are involved in regulating worm burdens they must operate at a very high threshold or alternatively immunity may be expressed selectively in a small resistant subset of the host population. Evidence in support of this latter hypothesis comes from observations that hookworm burdens are highly aggregated in affected populations, suggesting that some people may be more predisposed to infection than others. Several studies have confirmed that predisposition is marked. The inhabitants of villages in endemic environments treated for hookworms and re-examined several months later showed significant positive correlation between pretreatment worm burdens and those acquired after treatment. In other words, people with initial high worm burdens became more intensively infected after treatment. However, the results may also be explained through mechanisms other than immunity: behavioral predisposition to infection resulting from differences in standards of hygiene is one possibility. Wearing/not wearing shoes is another.

Volunteer infections

Several reports of infective larvae being administered to human volunteers have been published. Single-pulse primary infections with all three species of hookworm are well documented, but repeated infections have only been reported for *N. americanus*. In all the recorded trials secondary, tertiary and even quaternary were as successful as primary infections in respect of parasite establishment and survival.

Animal experiments

There is little doubt that both *A. caninum* and *A. ceylanicum* elicit strong protective immunity in dogs. Evidence is available for acquired immunity to *N. americanus* in a mouse model: in this case immune animals resist infection both at the skin site

of challenge and during the pulmonary phase of development.

Antibody responses in humans

Human hookworms elicit a variety of antibody responses in their hosts. These have been detected with a range of different assays including ELISA and radioimmunoassay. Responses to ES products and to surface cuticular antigens are particularly prominent and infection is often accompanied by a significant rise in particular immunoglobulin isotopes. Marked increases in total serum IgE are commonly observed in human cases of hookworm disease, often exceeding the quantities typical of patients with IgE myeloma disease. Most of the additional immunoglobulin in the circulation is not specific to parasite antigens and results from potentiation of unrelated IgE response, such as those to environmental antigens. An interesting study in India has reported a reduction in total IgA in the intestinal aspirates of hospitalized hookworm patients, followed by rapid restoration of normal levels when the worms were cleared by anthelmintic treatment, supporting the idea that hookworm proteases are able to digest host IgA and implying that this class of immunoglobulin poses a particular threat to the worms.

Analysis of age-dependent changes in antibody levels to stage-specific antigens of *N. americanus* and parasite burdens have produced some interesting results. In general, the greater the worm burdens the more intense the antibody responses to adult antigens. However, whilst in young children the relationship between antilarval IgG and parasite burden was consistently positive, in older age groups negative correlations were detected, implying that despite overall heavier worm burdens among older sectors of the community those who had fewer worms also had higher concentrations of antilarval antibodies and hence may have been resistant to further larval challenge. Data suggest that hookworms elicit T_H2-type responses with involvement of specific IgE responses to ES products and eosinophilia, but apart from an indication that the more intense responses are associated with smaller and less fecund adult worms there is little to suggest that the T_H2-dependent immunity has a major role to play in providing significant host-protective immunity to hookworms.

Cellular responses in humans

Few studies have investigated cellular responses to hookworms. Blast cell activity and reactivity to mitogenic as well as antigenic stimulation have been measured using human peripheral blood and bronchoalveolar lavage leukocytes. Increased reactivity was recorded but was confounded by considerable

variation between volunteers infected with *N. americanus*. However, significance differences in lymphocyte reactivity were observed during experimental human exposure to *A. ceylanicum* as well as in dogs during primary and secondary infections. Despite these studies, no clear picture has emerged from the use of techniques measuring lymphocyte activity, and the significance of changes in lymphocyte responsiveness are not understood in the context of host-protective immunity to hookworms.

Eosinophilia has been recognized for some time as a common manifestation of hookworm infection and impressive increases in the percentage of hypodense eosinophils have been described in volunteers with *N. americanus*. The same study revealed increased production of superoxide and enhanced chemotaxis of eosinophils from infected donors. Eosinophils have the capacity to adhere to L3 of *N. americanus* in *in vitro* systems. However, as above, a link between elevated eosinophil activity, and host-protective immunity to hookworms has yet to be established. Research on the cellular side of immunity to hookworm infection is a neglected aspect of this disease.

Evasive strategies by the organisms

It is clear from hookworm epidemiology and from experimental infections, that the parasites must employ evasive strategies to survive but information on possible strategies for evading the host's immune response is still scarce.

Several ideas have been put forward as to how immunity may be avoided but none of these has been established as a principal method of avoidance. *A. caninum*, for example, changes feeding sites within the host intestine at regular intervals, staying in place for no longer than 6 h at a time. Continuous relocation may be one way to minimize the effects of local inflammatory reactions as long as the gut does not respond to infection at a gross organ level. The identification of functional proteases in hookworms offers the intriguing possibility that some of these digest antibody on the parasite surface, a strategy utilized by many species of mucosal bacteria. The antioxidant enzymes of hookworms probably protect the worms from effector molecules released from local inflammatory cells. Hookworms may also cause general immunosuppression and probably utilize immunomodulatory molecules to downregulate immunological activity locally in the intestine as other gut nematodes are known to do. In *Ancylostoma* species, NIF may reduce local inflammation and undoubtedly other molecules with related or other immunosuppressive functions will be described

in future studies. However, such aspects of hookworm biology have only recently begun to be explored and it is still too early to present a realistic appraisal of their significance in overall avoidance of host immunity.

Vaccines

There are no vaccines for use against hookworm diseases in humans. However, a highly effective vaccine, based on the use of irradiated larvae, developed against *A. caninum* in dogs induced good protective immunity and it was considered that the tissue stages (possibly the lung phase) of the parasite provided the principal immunogenic stimulus as well as the main target of immunity following subsequent naturally acquired larval challenge. Vaccinated dogs were protected against anemia, but still harbored residual worms and the fact that sterile immunity was seldom induced contributed significantly to the commercial failure of the vaccine which was eventually withdrawn from the market.

Irradiated larval vaccines are never likely to be accepted for human use and the specificity of hookworms for their definitive hosts precludes the large-scale use of laboratory animals in supplying worms for antigenic preparation. Recent attention has therefore been focused on the scope for recombinant DNA technology as a solution to the provision of large quantities of relevant parasite antigens for research. Rapid progress has already been made and several genes encoding functional antigenic molecules have been cloned from *N. americanus* and *A. caninum*.

An alternative approach, which is being currently evaluated, is the development of cryptic epitope (also known as concealed or hidden antigen) vaccines. This approach has been shown to induce high levels

of protection in sheep against the blood-sucking nematode *Haemonchus contortus*. The basis of this vaccination strategy is to elicit in the host high levels of antibody against epitopes which the host normally does not have an opportunity to see, such as epitopes on intestinal cells of the parasite. When the worms then take a blood meal containing the antibodies their intestines are severely damaged and the worms may be expelled.

The next decade should see major strides in our understanding of hookworms and their host-parasite relationships as a consequence of the implementation of these new technologies.

hu-SCID MICE

Gianvito Martino and **Luigi ME Grimaldi**, Department of Neurology, University of Milan, San Raffaele Scientific Institute, Milan, Italy

The severe combined immune-deficient (SCID) mouse

The SCID mutation spontaneously occurs in BALB/c mice, where it impairs double-strand DNA break repair. V(D)J rearrangement is primarily affected, resulting in a defective coding joint formation which

prevents the development of mature B and T cells. The molecular consequence of the SCID mutation is a genetically determined deficiency of the DNA-dependent protein kinase (DNA-PK) which induces DNA break repair by forming an activated complex with the DNA end-binding Ku proteins (p80 and p70) upon association with the damaged DNA.

there is improved human lymphocyte trafficking from the SCID mouse peritoneal cavity to peripheral tissues.

Conclusions

Despite its drawbacks, the hu-SCID mouse chimera (mainly obtained by intraperitoneal transplantation of human lymphocytes) represents one of the most accessible models for studying some of the aspects of human autoimmune diseases and, in general, of the human immune system. Although long-term studies are probably hampered by the fact that the mouse thymic environment operates a T cell selection restricted to murine antigens (Figure 1), the continuing improvements in achieving a longer persistence of non-antimurine-reacting human cells in the SCID mouse after transplantation are encouraging and a better and more complete engraftment of human lymphoid cells into mouse organs able to sustain a correct lymphopoiesis is conceivable in the near future.

HUMAN IMMUNODEFICIENCY VIRUSES

Myra McClure and **Angus Dalgleish**, Department of GU Communicable Diseases, Imperial College School of Medicine, London, UK

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Within a decade, the virus causing the acquired immune deficiency syndrome (AIDS) emerged from obscurity to become the best characterized of all retroviruses, the first of such viruses to have its cellular receptor defined and the one which has proved

to have the most complex genomic organization. The many facets of current AIDS virology are such that only a 'thumbnail' sketch of the virus structure and its behavior can be outlined here.

Classification and structure

The etiological agent of AIDS, human immunodeficiency virus type 1 (HIV-1), now endemic worldwide, was discovered in 1983. Two years later, a second virus (HIV-2) that caused the same disease but was significantly different from HIV-1 serologically and molecularly to be considered a separate, but related, virus was discovered in West Africa. Between 1985 and 1989, several nonhuman primates were shown to harbor similar viruses, some of which cause disease in the natural host and some of which appear to be quite harmless. All of these viruses have an RNA genome and replicate via a DNA intermediate (a 'provirus') by means of viral RNA-directed DNA polymerase, more commonly called reverse transcriptase. It is this 'backward' transfer of genetic information from RNA to DNA which classifies these viruses as retroviruses.

Each virion measures approximately 120 nm in diameter and has condensed cylindrical core surrounded by a lipid membrane. The envelope 'spike' glycoprotein is embedded in and protrudes from this membrane. The interrelationship of genomic RNA, core proteins and surrounding envelopes is more clearly demonstrated schematically (Figure 1) and more readily understood by considering the genomic organization.

Structural and functional organization of the HIV-1 genome

The HIV virion contains two identical copies of single-stranded RNA, 9.2 kb in length, of positive polarity with respect to translation. The proviral DNA resulting from reverse transcriptase has three genes which code for the virion structural proteins: gag, pol and env encoding the core proteins, enzymes for viral replications, and the envelope glycoproteins, respectively. Each gene product is initially synthesized as a high molecular weight polypeptide precursor which is subsequently proteolytically cleaved to yield the final, smaller structural components of the virus.

The genome (Figure 2) contains at least nine genes, flanked by long terminal repeat sequences (LTR) containing promoters of gene expression and specific enhancer elements which control viral gene expression and which are themselves influenced by cellular transcriptional proteins.

HIV structural genes

The primary product of the gag gene is a 55 kDa precursor polypeptide (p55) which upon proteolysis yields p17, the myristylated matrix protein (MA), and antigens of the viral core, the capsid (CA) p24,

Figure 1 Schematic representation of an HIV virion. The relative positions of HIV structural and other virion proteins are indicated. NC, nucleocapsid; CA, capsid; RT, reverse transcriptase; IN, integrase (endonuclease); MA, matrix; TM, transmembrane; PR, protease; SU, surface.

Figure 2 Genomic organization of HIV-1 and HIV-2. The genomes, which are between 9 and 10 kb long, are flanked by long terminal repeat (LTR) sequences. The *vpu* gene is only found in HIV-1 and the closely related simian virus from the chimpanzee, *SIV_{cpz}*. The *vpx* gene is common only to HIV-2 and its related simian counterparts isolated from the macaque and the sooty mangabey monkey, *SIV_{mac}* and *SIV_{smm}* respectively.

the nucleocapsid (NC) p7 and p6 which facilitates virion budding from the cell.

Since the *gag* and *pol* genes overlap in different reading frames (Figure 2), translational frameshifting is necessary to produce the Gag-Pol polyprotein precursor (p106) which also undergoes proteolytic cleavage by the virus-encoded protease to produce 1) the protease (p10) responsible for the breakdown of p55 *gag*, 2) the enzyme reverse transcriptase, p66 and p51, and 3) an endonuclease or integrase (p32) to catalyze the integration of the provirus into the chromosomal DNA of the host cell. Thus, both the Gag and Gag-Pol precursor proteins are broken down to their final products by the same protease, p10, during or after budding from the cell surface.

The initial 160 kDa glycoprotein product of the *env* gene undergoes cleavage to leave a newly glycosylated surface (SU) protein of 120 kDa (gp120) at the N-terminus, and the C-terminal gp41 transmembrane envelope glycoprotein. The viral gp41 serves to anchor gp120 to which it remains noncovalently attached and to effect membrane fusion via a hydrophobic domain at its N-terminus.

HIV regulatory and accessory genes

In addition to the usual three retroviral structural genes, the HIV-1 genome includes six further genes encoding regulatory and accessory proteins translated from various multiply-spliced HIV RNAs. The three genes regulating virus replication are *tat*, *rev* and *nef*. Two of these genes, *tat* and *rev*, are nuclear proteins which are absolutely essential for virus replication. Proviruses defective in these genes fail to replicate. The two exons of the *tat* gene code for a 14 kDa diffusable effector protein which binds directly to specific responsive sequences (the transactivating responsive region, TAR) within the LTR. In so doing, the synthesis of both structural and regulatory viral proteins is either directly or indirectly increased at the level of transcription initiation, elongation or both.

Viral structural protein synthesis is additionally controlled by the action of the *rev* gene, the 19 kDa phosphorylated product of which is located within the nucleolus and binds to Rev response elements (RRE) located within the *env* gene. The functional

expression of the Rev nuclear protein acts to facilitate the transport from the nucleus to the cytoplasm of multiply-spliced transcripts encoding regulatory proteins (Tat, Rev, Nef, Vpr) early in infection, or unspliced or partially spliced mRNA from which the Gag and Env proteins are translated.

The *nef* gene encodes a 27 kDa myristylated protein which is highly conserved in all immunodeficiency virus genomes (HIV-1, HIV-2 and the SIVs), yet is not essential for replication of the virus *in vitro*. Its importance would appear to be connected to its role in pathogenesis *in vivo*, since macaques infected with *nef*-deleted mutants fail to develop simian AIDS.

The remaining accessory genes, *vif*, *vpr*, *vpu* and *vpx*, which are dispensable for *in vitro* replication of the virus are, nevertheless, highly conserved in HIV and SIV strains, suggesting that, like *nef*, these genes have an important role *in vivo*, either in contributing to the efficiency of virus replication or to the pathogenic effect of the virus in the infected host. The *vif* and *vpu* genes contribute to virus replication by increasing the efficiency of infection of cell-free virus (*vif*) and in facilitating the assembly, binding and release of mature virus particles (*vpu*). In the absence of *Vif*, the 23 kDa cytoplasmic gene product which associates strongly with the cell membrane, virions have an abnormal morphology and a reduced capacity to synthesize proviral DNA when they infect new cells. Only the HIV-1 genome and that of the closely related chimpanzee immunodeficiency virus, SIV_{CPZ}, contain the *vpu* gene, the 16 kDa phosphorylated gene product of which is located outside the nucleus, close to the endoplasmic reticulum (ER) and Golgi apparatus. It appears to direct the transport of envelope proteins to the cell surface by mediating degradation of CD4 molecules in the ER. Mutant virus deficient in *vpu* replicates *in vitro* at reduced titer due to the accumulation of virus particles in intracytoplasmic vesicles.

The *vpr* gene induces subtle increases in the kinetics of virus infection. It appears to enhance virus production in primary macrophages and, to a lesser extent, in some T lymphocyte cell lines. The *vpx* gene is present in HIV-2 and the SIVs, but not in HIV-1 and, like *vpr* is packaged within the virion. Its function is ill-defined.

The lifecycle of HIV

Infection by HIV is initiated when either cell-free or cell-associated virus binds to a receptor in the target cell by means of the virus envelope. The major receptor for HIV, CD4 (see below), is a membrane protein

found on the surface of certain hematopoietic cells, such as T helper lymphocytes and monocytes.

After fusion of the virus envelope protein with the cell membrane, the virus core enters the cell and single-stranded RNA, still associated with capsid protein, is converted to double-stranded proviral DNA through the dual polymerase and ribonuclease activities of the viral reverse transcriptase.

In T cells, the newly made provirus then enters the nucleus, integrates with host DNA by the action of the viral integrase and establishes an infection which is lifelong. The proviral DNA acts as a template for the production of viral RNA. This, in turn, serves both as messenger for synthesis of new viral proteins and as genomic RNA which is subsequently packaged into viral particles. Virus assembly occurs at the surface of the membrane. First, the capsid protein condenses beneath the cell membrane to form the budding particle. The viral RNA attached to the capsid precursor is folded into the particle while the envelope protein aggregates on the outer surface. The virus particle is then released from the cell surface and the capsid protein is processed into mature proteins by the viral protease. This completes the life cycle.

Replication of HIV is determined at least in part by the level of activation of the target cell. It is well established that HIV will not replicate in resting T cells, one level of restriction is at the level of provirus synthesis. Apparently, only a partial provirus is formed in the resting cell and upon activation provirus goes on to completion. Another restriction is at the level of RNA transcription. The HIV LTR contains binding sites for at least two transcription factors which are activated in stimulated T cells. These are Sp1 and NFκB. Interaction of one of these two factors with the LTR sequences is sufficient to confer the virus with responsiveness to mitogenic stimulation. A number of DNA viruses (CMV, HSV), as well as the human T cell leukemia virus (HTLV-1), have been shown to activate the NFκB site. Many other cellular factors bind to specific DNA sequences in the HIV LTR and conceivably regulate HIV expression. The abundance and variety of these factors will vary according to cell type and cell cycle.

The HIV receptor

The CD4 molecule is a T cell surface glycoprotein of 55 kDa that characterizes the T helper subset of the human lymphocyte population. It associates with major histocompatibility complex (MHC) class II molecules on the surface of antigen-presenting cells to effect a humoral and cellular immune response.

Classically, three main lines of evidence clearly

established CD4 as an essential component of the HIV receptor. First, monoclonal antibodies directed against the CD4-binding site completely inhibited infection of susceptible cell lines. Second, it was shown that the envelope glycoprotein of HIV-1, gp120, binds specifically and with high affinity (K_d 10^{-9} M) to the CD4 molecule on T helper lymphocytes. Third, transfection of the CD4 gene into non-susceptible (i.e. nonlymphoid) cell lines of human origin rendered them infectible by HIV. Cells of non-human origin, however, remained refractory to infection, leading to the idea of a species-specific cell surface cofactor in addition to CD4 being required for viral entry. Subsequent studies showed that strains of HIV-1 that had been adapted for growth in transformed T cell lines (T tropic strains) could infect primary T cells, but not primary monocytes or macrophages. In contrast, many primary viral strains were found to infect monocytes, macrophages and primary T cells, but not transformed T cell lines. This difference in tropism which results from sequence differences within the variable domains of the outer envelope glycoprotein, gp120, suggested that multiple cell type-specific cofactors might be necessary for entry, in addition to CD4. The molecules in question turned out to belong to the family of seven transmembrane signal transduction receptors for chemoattractant cytokines (chemokines). Interestingly, while many unsuccessful attempts had been made to molecularly clone the HIV entry coreceptor, it was the clinical observation that individuals who were homozygous for a 32 bp deletion in the chemokine receptor CCR5 were resistant to HIV-1 infection which led to the recognition of CCR5 as a coreceptor for macrophage-tropic (M-tropic) HIV-1 strains. Other strains adapted for growth and syncytium induction in transformed T cell lines (T tropic strains) utilize the CXCR4 receptor.

All HIV-1 strains tested *in vitro* use either CCR5 or CXCR4 coreceptors or both, suggesting that these coreceptors are likely to be determinants of infection and pathogenesis *in vivo*. However, receptor usage by HIV-1 is not restricted to either of these molecules. Many strains can use other members of this receptor signaling family, such as CCR3, CCR2b, and some even utilize the recently identified SIV coreceptors currently called 'Bonzo' and 'Bob' (brother of Bonzo!). The rather flippant nomenclature reflects both the freshness of their discovery and the anonymity of their natural ligands, although since each appears to be identical to known receptors, Bob may be known as GPR15 and Bonzo as STRL33.

In all, six coreceptors which are exploitable by HIV-1 for host cell entry are now known. These have

all been identified from experiments carried out *in vitro*. Currently, the extent to which they are used by the virus *in vivo*, or the selective pressures existing to influence their use are not understood. Since this active area of investigation has only recently opened up, much remains to be learned about the contribution of each coreceptor to the determination of infection, the pathogenic sequelae and about how a knowledge of coreceptor usage can be exploited for drug development.

Antigenic variation in HIV

With the availability of extensive HIV nucleotide sequence data, genetic diversity among AIDS viruses can be compared. The envelope gene of HIV-1 contains five hypervariable regions which are flanked by conserved regions. Sequence diversity is a characteristic of many RNA viruses. They are genetically error-prone by virtue of their DNA-dependent RNA polymerase, a step in their replication cycle which escapes correction by host cell enzymes ('sub-editing'). It has been estimated that the HIV-1 reverse transcriptase transcribes on average one error per genome in each replication cycle. These errors are mainly point mutations producing amino acid substitutions, stop codons, etc., although insertions and deletions have also been observed.

Genetic variability leading to antigenic diversity are means by which viruses can evade immune surveillance. For example, as well as retroviruses, influenza virus does this very successfully by generating an ever-changing repertoire of antigens. For many lentiviruses, genetic variation offers a selective advantage by allowing adaptation to different biological environments. If such variation is subjected to immune selection resulting in temporary evasion of host defense mechanisms, variant viruses result. Genotypic variation has been noted within a 'single isolate' of HIV-1 (i.e. taken from one individual), among isolates taken over time for the same individual, and among very different isolates within populations. Such variation is rapid *in vivo*, producing a great many related but distinct genotypes which can evolve in parallel and coexist during chronic infection, raising the possibility of the emergence of viruses with recombinant genomes. Thus, in addition to rapid mutation, recombination can contribute to the genetic diversity which characterizes the AIDS virus.

Since the discovery of the virus in 1983, the HIV-1 genome has been extensively studied, partly to determine the range of strains contributing to the global epidemic (and this information has obvious implications for vaccine design and evaluation) and

partly in an attempt to understand the evolution of HIV-1 over time. On the basis of sequence analysis and alignment of the gag, env and tat genes chosen from diverse geographical isolates of HIV-1, two major groups have emerged: group M, the major group comprising most isolates, and the distant (about 50% within env) group O or 'outlier group'. Even within the 'O' group, the HIV isolates are not closely related, being approximately 30% different from one another in their env gene sequences. Within the major group, the HIV-1 isolates can be subdivided into at least 10 genetic subtypes called clades (A–J). All subtypes are approximately equidistant from one another, the distance separating them being about 30% in the env and 14% in the gag gene. For comparison, HIV-1 and HIV-2 differ by at least 50% in both genes. On a similar basis, HIV-2 isolates can be classified into five clades.

Recombination between isolates of different clades makes its own contribution to the range of strains found in the global pandemic of AIDS. It is calculated that at least 10% of reported HIV-1 strains represents mosaic (recombinant) forms of the viral genome, i.e. bearing sequence characteristics of two different genetic subtypes. This can occur at any point along the genome and recombination break-points have been mapped in the LTR, structural and regulatory genes. For example, subtype E viruses mainly found in South-East Asia are really recombinant viruses composed of genetic material from subtype A and from an undefined parental subtype. The existence of recombinant viruses suggests that HIV-1 strains of different clades can coexist in the one individual, resulting in viable infectious progeny viruses of mixed genetic background, all of which adds to the dynamic and unstable nature of the HIV-1 epidemic worldwide and to the difficulties of designing an all-purpose vaccine.

The immunology of HIV infection

The immunology of HIV infection at first sight appears to be simple: HIV targets CD4⁺ cells, resulting in a declining CD4 cell count and loss of CD4 helper T cell function. As the CD4 lymphocytes are so pivotal to the immune system, providing help for other functions directly or through cytokines, it is not surprising that other immunological functions also decline as disease progresses. However, as more HIV⁺ people are studied in more detail for longer, it is clear that the pathogenesis and the nature of the protective immune response are considerably more complicated than originally perceived. The most antigenically dominant domain on the envelope of HIV, the V3 loop of gp120, induces neutralizing

antibodies and this factor has driven vaccine development. Because this region is highly variable, the virus is able to escape a strong antibody response. Moreover, it is not clear that disease progression is greatly influenced by neutralizing antibodies on their own as the immune response broadens to different V3 loops as disease progresses. Therefore, the nature of the protective immune response that clearly exists in long-term partners of AIDS patients must be defined in detail and the mechanism of how the virus induces disease needs to be carefully elucidated. Unfortunately, after over a decade of research the answers to these questions are only just beginning to be more than just theoretical.

The immune response to HIV and the correlates of protection

HIV induces neutralizing antibodies, antibody-dependent cellular cytotoxicity (ADCC), and cytotoxic T lymphocyte (CTL) activity in infected hosts. Unfortunately, it remains unclear as to whether any one, or all, of these activities can prevent infection and disease progression in the majority of individuals. It is important to appreciate that the quality of the immune response that protects against infection and the type of response required to contain infection may be different. This, of course, will have important implications for the development of preventative and therapeutic vaccines. This problem is further compounded by the fact that HIV-infected chimpanzees do not appear to develop an AIDS-like disease, and hence they may have a vital immunological difference that allows a vaccine to prevent HIV infection that will not extrapolate to protection of humans against the same infection.

Over the last few years it has become evident that a number of people have been consistently exposed to HIV but have remained seronegative, and that others have seroconverted but remained disease free. Studies on these patients show that they are more likely to have a strong cell-mediated or T_H1 cytokine profile (IL-2, IFN γ and IL-12) than those who develop disease. Moreover, they have good mucosal immunity and higher IgA levels as well as antibody responses to the C-terminus of gp120. The CTL response is confusing, as although CTL responses would expect to contain the virus, the activity is often low (and indeed hard to detect at all in HIV-1-infected chimpanzees).

The HIV vaccine challenge

The principle of vaccination is straightforward: the inoculation of a safe antigen to induce an immune

response against the etiological agent of an infectious disease and in doing so confer protection to subsequent infection. Successful vaccines currently available against virus-induced diseases include live attenuated strains that produce infection without inducing disease, such as the Sabin polio vaccine. Such strategies are not practically applicable to HIV-1 because the safety of attenuated strains cannot be evaluated before use. Even extensive genetic modification (e.g. deletion of regulatory genes critical for virus replication) would not necessarily ensure against reversion of the virus to virulence. While this strategy of vaccination with mutants deleted of key regulatory genes protected adult macaques from experimental SIV challenge, it proved fatal to immunocompromised neonatal animals.

An alternative strategy is the subunit vaccine which has already proved successful for viruses such as hepatitis B. In this respect the advent of recombinant DNA technology has allowed vaccine development to enter a new era. Individual virus genes can now be cloned and expressed in prokaryotic and eukaryotic cells to yield enough antigen for subsequent purification and use in vaccine studies. The viral proteins most likely to be exploited as compound candidate vaccines are those of Env and Gag. Antibodies directed against gp120 can neutralize HIV *in vitro*, while Gag protein has been shown to have epitopes recognized by both helper and cytotoxic T lymphocytes.

Neutralization epitopes of HIV-1 fall within the five hypervariable regions (V1-V5) of the envelope glycoprotein, gp120 and gp41, with the major neutralization epitope lying within the V3 domain. Serum and monoclonal antibodies directed against this region neutralize free virus infectivity and syncytium formation resulting from the coculture of HIV-infected cells with uninfected CD4⁺ cell lines. The amino acid sequence of the V3 neutralizing domain can elicit group-specific antibodies, i.e. antibodies which are effective in neutralizing a narrow range of HIV-1 isolates *in vitro*. In addition to being the principal neutralization epitope, V3 is an MHC class I restricted CTL epitope and a helper T cell epitope. *In vitro* studies have demonstrated that a minor mutation within the env gene can significantly alter the sensitivity of HIV-1 to neutralization. This implies that viral heterogeneity and immune selection *in vivo* allows HIV-1 to escape immune surveillance, leading to disease progression in the presence of neutralizing antibodies.

A major difficulty facing vaccinologists is that primary or field isolates of HIV-1 (i.e. those that have not adapted to growth in cell culture) are relatively resistant to neutralization by antibody. At the

same time, certain monoclonal antibodies and sera collected from infected individuals have the ability to neutralize some field isolates. The principal determinant on primary viruses against which neutralizing antibodies are raised has not yet been identified. Consequently, nothing is known of the breadth of these effective reagents or the extent to which this putative principal neutralizing domain would be present in primary isolates from different clades. Nevertheless, in the absence of defined correlates of protective immunity to field isolates of HIV-1, it must be assumed that high titers of specific neutralizing antibody and a significant cell-mediated response should ideally be induced in the immunized host. Since gp120 carries the major neutralizing determinant and the major CTL epitopes are located in the Gag, Pol and Nef proteins, it would suggest that a 'cocktail' of antigens may be more effective than a single component. A number of candidate vaccines have already been shown to be capable of inducing CTL response to HIV-1, among them live viral vectors delivering envelope genes, e.g. vaccinia-gp160 or avipox gp160, both used with a recombinant gp120 booster.

Whatever the adopted strategy for the development of an HIV vaccine, many complicating factors must be taken into account:

1. It is not yet known what combination of viral proteins in a subunit vaccine could best mimic the response induced by whole virus particles. Moreover, monomeric gp120 subunits, a likely vaccine component, may not reflect the more complex native envelope structure in the virus particle.
2. HIV can be spread by cell-free virus in the bloodstream or by the fusion between infected and uninfected cells. Both are important routes of infection and any potential vaccine candidate would have to have the capacity of preventing infection by both routes.
3. Testing the safety and efficacy of a new HIV vaccine before its general use may well present a considerable problem. There is no ideal animal model of HIV infection. Chimpanzees have been experimentally infected with HIV-1, but they do not manifest signs of clinical disease. Putative vaccines could, of course, be tested for their ability to inhibit infection, but this does not provide the ideal *in vivo* experimental system. An alternative approach would be to run parallel studies using the SIV-macaque system. Indeed, the most convincing evidence yet that a vaccine against HIV will prove possible has been the protection of macaques from simian AIDS fol-

lowing immunization with formalin-inactivated SIV particles.

4. Any useful vaccine must have a broad specificity of action. A strain-specific response which would protect only one strain of a mutation-prone virus would be futile. However, recent work investigating the neutralization properties of three human monoclonal antibodies against 10 viruses from a number of different clades suggests that an immunogen able to elicit significant neutralizing activity against a representative set of primary isolates from one clade, may also be able to induce a cross-clade response. This remains to be further investigated.
5. As candidate vaccines become available for evaluation, moral, ethical and safety considerations will simultaneously raise difficult issues concerning the use of primates and of human subjects in such studies. For example, HIV diagnosis is carried out serologically by ELISA and confirmatory western blot. In the event of a multicomponent vaccine entering a clinical trial, the question of distinguishing those subjects who are seropositive from those who have been immunized becomes problematic.
6. The generation of 'enhancing' antibodies which could increase viral infectivity needs to be avoided.
7. CTL activity could also be more harmful than helpful depending on the other factors operating within the immune system at the time.

In order to understand some of these issues, the pathogenesis of HIV will be reviewed.

How HIV causes disease

The correlates of disease are easier to identify than the correlates of protection and have been well documented by many investigators. Studies on the early stages of disease at the time of infection and seroconversion show that the viral load and the nonspecific activation markers of the immune system such as soluble TNF receptor levels are both highest in those that progress to disease rapidly. However, even in those who progress rapidly towards disease the high initial virus load is quickly reduced, presumably by the immune response, although the intrinsic dynamics of viral replication could also explain at least part of the decline. It may be that the initial interaction between the virus and the immune response sets the future pattern of disease. The issues affecting the establishment of infection at this stage are numerous and include properties of the virus as well as the host. Nonspecific sera and complement factors may play an initial role and the responsive-

ness of the immune system is probably also critical. A number of studies have reported a strong link between HIV disease progression and nonspecific activation of the immune system. Not only is there a close association with the rate of progression to disease, but also the baseline activation associated with immunogenetic markers such as the HLA system itself determines the rate of disease progression.

Immune activation and disease

Retroviruses are not particularly virulent viruses, at least in the short term. In order to infect cells and increase their chances of establishing a high viral load they prefer activated cells and employ sophisticated mechanisms to activate resting cells. Some retroviruses encode a superantigen which can activate approximately 10% of the T cell population. In spite of some publications to the contrary, there is no good evidence that HIV encodes a classic superantigen. Some authors maintain there is no need to encode a superantigen as the virus turns over fast and varies its dominant antigens, thus multiply stimulating the immune response. A disease which causes immunodeficiency by pan-activation and concomitant immunosuppression is chronic graft-versus-host disease (CGVHD). This is of interest with regard to HIV, as prior to the identification of HIV, the clinical similarities between AIDS and CGVHD had been recognized and the role of alloantigens in semen and blood proposed as an activation stimulus. Although this is extremely unlikely, the fact that HIV encodes several HLA-like regions makes the possibility that the virus itself induces allostimulation intriguing. The concept has recently been supported by the ability to induce murine AIDS with chronic, repeated stimulation with alloantigens. It is of further interest that several of the specific immune defects are similar, such as the early loss of antigen-specific responses.

HIV: virus turnover

The ability of HIV to kill CD4 cells directly and indirectly (such as by the signaling of apoptosis and the induction of fusion by envelope contact) should in itself be enough to gradually reduce the CD4 count. However, the rate at which it can do so has been questioned, and the need to invoke other mechanisms in addition to direct cytopathic effects has been raised by a number of authors. The ability to perform accurate quantification of viral load has allowed the new antiretroviral therapies to be assessed in detail. Such studies have allowed the overall rate of virus turnover and the half-life of the

virus, a virally infected cell, and the time from budding from one cell to virus release from a newly infected cell to be calculated. There were some surprises: the amount of virus turning over in the peripheral circulation per day was in the region of 10^9 to 10^{10} , the half-life of the virus less than 6 h, the half-life of productive cells was 1.6 days, and the time from budding to productive infection, 2.6 days and the half-life of long-lived cells was 1–4 weeks. Based on these calculations and the response to therapy, it has been calculated that effective treatment would need to be given for about 3 years.

The finding that the virus has such a high turnover rate suggested an immediate explanation for the CD4 cell decline *in vivo*. However, it may be that the decline is very slow, even with this turnover rate which would need to influence the precursor compartment before any effect on the CD4 cell numbers would normally be seen. In this regard a reservoir of HIV exists within follicular dendritic cells in the lymph nodes, as well as in mononuclear cells in the periphery and the spleen. It is the former that probably contributes most to the circulating virus load.

A major source of controversy has been whether or not HIV kills cells directly or indirectly. Although HIV can kill cells readily *in vitro* by inducing fusion and cytopathic effects, the indirect effects whereby apoptosis is induced without productive infection may also play a major role in the disease. The ability to infect antigen-presenting cells would greatly enhance this ability as well as interfering with antigen-presenting functions directly. The presence of gp120 alone during antigen presentation can inhibit antigen-specific responses, and this coupled with the ability to infect the most potent antigen-presenting cells would allow for a major perturbation of normal immunological function.

Immunogenetics and the cytokine system

The association with different HLA types and disease progression has been reported in most cohorts studied, although only a few of the associations stand up to multicenter analysis. One of the most striking associations is the association with HLA-B27 and nonprogressors and in Caucasian populations the association of HLA-A1, B8, DR3 with more rapid progression to disease. The latter haplotype is also associated with enhanced baseline immune activation that in turn is associated with other diseases of chronic activation such as systemic lupus erythematosus (SLE). It is of some interest that chimpanzees, which are 98% genetically similar to humans, do not have these haplotypes associated

with disease progression. The haplotypes determine a number of immune responses apart from peptide selection, including cytokine and complement usage. The fact that nonprogressors and chimpanzees have a quiet T_H1 -type immune response may be important with regard to the conditions that determine the initial interaction between the virus and the immune system. The loss of T_H1 responses is associated with progression and several authors report a T_H2 -dominant response as disease progresses although this also appears to become deficient with time in that IL-4 *per se* also disappears, leaving IL-10 and TNF more dominant.

A major issue is whether or not the immunological perturbation of HIV infection can be permanently correctable with antiviral treatment and whether or not an effective immune response can be induced, allowing this therapy to be withdrawn. Many patients have a dramatic 2-log decrease in viral load with therapy accompanied by a rise in the CD4 cell count. Unfortunately, attempts to stop therapy leads to a bounce back in viral load within 2–4 weeks. Even patients who are benefiting from therapy may have progressive disease of some associated condition, such as Kaposi's sarcoma, suggesting that immune competence may require 'reprogramming'; for example by inducing a T_H1 -dominant response.

The fact that much of the immune response is activated as disease progresses would suggest that if this is causal, then immunosuppression should be beneficial. There are suggestions that this may be so: studies with steroids and cyclosporine have suggested a delay in disease progression and lymph node radiotherapy, an effective form of immunosuppression, has prevented disease progression in SIV-infected macaques.

The immunology of HIV is clearly complicated and no single issue would appear to be of overriding therapeutic importance, other than the complete elimination of all virions. However, even this may not reverse immunodeficiency if irreversible changes in the immune system have been induced. Nevertheless, the following major points are worth summarizing:

- HIV only causes disease in susceptible hosts who bear the CD4 receptor and the appropriate secondary receptors, such as CCR5.
- The immune response appears to be genetically controlled and can determine outcome in that a cell-mediated T_H1 response is associated with a better prognosis than a T_H2 -dominant response.
- An activated immune system and a vigorous immune response to the virus are often associated with progressive disease.

HUMANIZED ANTIBODIES

William J Harris, Department of Molecular and Cell Biology, University of Aberdeen, Marichal College, Aberdeen, UK

The techniques for humanization of antibodies originated in 1986 when Jones and his colleagues demonstrated that antigen binding specificity could be transferred from a mouse monoclonal antibody into a human antibody by replacing the complementary determining regions (CDRs) of the human antibody with those of the murine – called CDR grafting. Subsequently it was found that in most cases additional subtle alterations to the structure of the human antibody were necessary to completely restore antigen binding affinity. The processes of introducing changes in addition to CDR grafting is called reshaping human monoclonal antibodies or humanization of antibodies.

Application of such techniques became possible with the development of methods for rapid cloning, sequencing and expression of antibody genes in mammalian cell lines and major advances in understanding the structure and computer graphic modeling of antibodies. In particular, the domains of the antibody which interact to provide the antigen binding surface were elucidated.

The rapid widespread use of the technologies in recent years has been driven by the disappointing behavior of rodent monoclonal antibodies as *in vivo* imaging and therapeutic agents and the continual failure to develop methodologies for routine provision of high-affinity human monoclonal antibodies.

Antibody-based therapies are attractive clinical and commercial targets. Over the last 20 years, many thousands of rodent monoclonals have been produced by hybridoma technology, many against unique targets of clinical significance. Humanization is perceived as the way to develop these as successful human therapeutics.

General background

Serum therapy using human immunoglobulins as intravenous immune globulin (IVIG) has been used successfully in a number of disease states. However, such polyclonal sera is expensive to collect, particularly high titer sera against specific diseases, and problems of contamination with viruses such as hepatitis B and human immunodeficiency virus limits the use of human materials.

In the last 15 years, over 50 different rodent monoclonals have been evaluated in studies of imaging (tumors, blood clots) and therapy (tumors, blood clots, immunosuppression). While the data show that these monoclonals can effectively target *in vivo*, they

have not proved clinically successful except in a few specialized cases.

Clinical use is limited by three factors. First, short serum half-lives of only 15–50 hours mean that regular repeat dosing regimens would be required, making the cost of treatment excessive. Human antibodies by contrast have serum half-lives of several weeks. Second, the effector function recognition signals for complement-dependent lysis of targets or Fc receptor driven cytotoxicity which reside in the constant region of rodent antibodies are not efficiently recognized by the human immune system. Thus other killing moieties such as radioactive isotopes or toxins have been attached to rodent antibodies, thereby increasing their toxicity. Third, the human immune system recognizes the rodent antibody as foreign and mounts a human antimouse antibody (HAMA) response, resulting in patient antibodies against the rodent monoclonal. HAMA responses develop in about 50% of patients after a single dose and in about 90% after a second treatment. Subsequent doses of antibody are then removed before they reach the disease target.

The aim of humanization is to provide antibodies essentially free of the three limitations on clinical use described above. Over 100 antibodies have now been humanized as a means of exploiting the existing vast array of rodent monoclonals as human therapeutics.

General structure of antibodies

The antigen binding site is in the Fab fragment and the effector functions in the Fc fragment. Six segments (CDRs) within the variable regions (V_H and V_L) of the heavy and light chains loop out from the framework (FR regions) globular structure of the rest of the antibody and interact to form an exposed surface at one end of the molecule (Figure 1). This is the antigen binding domain. Generally 4–6 of the CDRs will be directly involved in binding antigen, although fewer than this will provide the main binding motifs.

CDR grafting

The first step in humanization is CDR grafting (Figure 2). This involves five steps.

1. Amplification of cDNA for heavy and light variable chain genes of any murine hybridoma is possible using the polymerase chain reaction and a small subset of synthetic oligonucleotide primers with a small level of degeneracy which will amplify all families of murine V genes.
2. Amplified genes are sequenced and synthetic oli-

Figure 1 Computer graphic model of the structure of the V_H component of NEWM human antibody. The CDRs loop out from the scaffold structure of the framework regions (blue) to provide the antigen binding surface at one end of the molecule. The framework residues marked are those most commonly involved in maintaining the correct conformation of the CDR loops. (Reproduced with permission from Harris and Cunningham (1995).) (See also color Plate 9.)

Figure 2 The method of CDR grafting of antibodies. Genes encoding CDR sequences from a donor rodent monoclonal antibody are sequenced. Synthetic oligonucleotides representing these sequences are then chemically synthesized and used to replace the corresponding CDRs in selected previously cloned human acceptor V_H/V_K genes. CDR grafted V_H/V_K are introduced into expression vectors, human constant genes of choice attached and the intact antibody expressed in mammalian cells.

gonucleotides which span the six CDR regions are synthesized. Earlier work selected CDR sequences as defined by Kabat on the basis of linear amino acid sequence homology across a range of antibodies. However, there are discrepancies between these sequences and loop segments and it is better to select those regions which encompass the loop structures.

3. The six synthetic oligonucleotides are synthesized with approximately 15 additional nucleotides at each end which are complementary to the corresponding nucleotides in the human immunoglobulin V genes chosen as acceptor molecules. These regions of homology then provide annealing sites for replacing CDRs in the human antibody with murine CDRs by oligonucleotide-directed mutagenesis.
4. Humanized V_H and V_K genes are cloned into separate expression vectors which include effective promoter and enhancer elements such as immunoglobulin (Ig) signals and human constant domain genes of choice (IgG1, IgG2, IgG3, IgG4), usually as genomic constructs. V_H and V_K vectors are cotransfected for permanent expression into cell lines such as mouse NS0, rat YB20, or CHO cells. Expression levels are of the order of 5–15 µg ml⁻¹.
5. It is usual for an initial CDR-grafted antibody

to have reduced antigen binding affinity compared to the parental rodent monoclonal. A number of alternate constructs are usually made with additional changes, particularly in the V_H framework regions (see below). These modifications are commonly screened by transient expression in COS or CHO-K1 cells.

Methods of humanization

The high-affinity binding of antigen shown by a monoclonal antibody is achieved by the loop structures in the antigen binding site being in the 'correct' conformation. This conformation is determined to some extent by interaction with certain residues in the underlying 'framework' region of the antibody (Figure 1). These loop-framework interactions may not be retained in an initial CDR-grafted antibody and therefore they do not generally have the same binding affinity for antigen as the original murine antibody.

Although the structure of loops can be assigned within a limited number of canonical forms, computer graphic modeling is not sufficiently developed to permit prediction of the 'correct' loop conformation and it is not known which loops provide the main binding energies to antigen. For these reasons

indirect methods have been developed to restore antigen binding affinity to a humanized antibody.

A major aspect is the selection of human V_H and V_K genes as acceptor molecules. A wide range of adult human immunoglobulin genes have been cloned which represent all seven families of V_H and V_K in the human genome and the entire germ line repertoire of human V_H and V_K has been sequenced. Two general strategies for humanization have been developed to exploit these resources.

1. CDR grafting using human V_H and V_K frameworks with the highest linear amino acid sequence homology to the donor rodent frameworks (homology matching). With this approach, the likelihood of the human framework having the same amino acid residue as the rodent in a 'crucial' position is maximized. Different human V_H and V_K combinations are used with each antibody and may include combinations not used in nature.

Table 2 Representative examples of humanized antibodies in cynomolgous monkeys and humans

Antibody	Doses (mg kg ⁻¹)	Monkeys		Man	
		t _{1/2} (hours)	M anti-mouse response (%)	t _{1/2} (hours)	HAMA
Anti-Tac	0.05–5.0	214	10–20	138	0/12
Anti-TNF α	0.05–1.0	66	10–20	150	0/20
RSHZ19	0.05–5.0	500	10–20	550	0/12
Murine antibody	1.0–10.0	50	100	50	8/10

Adapted from Harris and Cunningham (1995).

- CDR grafting using a limited subset of human framework V_H and V_K combinations selected on the basis of common usage *in vivo* (fixed frameworks). Those most commonly used are human NEWM V_H and REI V_K. These frameworks are used irrespective of linear amino acid sequence homology with the donor rodent antibody.

In both cases a few additional murine framework residues may have to be introduced. These are usually drawn from a small subset of residues 'critical' for framework–CDR interactions. Many have been defined by comparative analysis of X-ray crystallographic studies of antibodies or predicted from computer modeling (Figure 1).

Nearly 100 antibodies have been humanized by these two methods and, if care is taken, antigen binding affinity can be restored with the inclusion of only a few (1–5) additional murine framework residues. *In vitro* antigen binding affinity as measured by ELISA is usually equivalent or 2–5-fold reduced compared with the parental rodent antibody, although higher affinity is occasionally achieved. Evidence is accumulating that *in vitro* ELISA assays are not necessarily an accurate predictor of *in vivo* activity and humanized antibodies with apparent 3–5-fold reduced *in vitro* affinity are equally effective *in vivo*. It is likely that restoration of 'off rate' is a more meaningful predictor and this can now be measured with biosensor technology.

Veneered antibodies

An alternative method of humanization is described as veneering or resurfacing and aims to replace the surface exposed amino acid residues on the rodent monoclonal with corresponding residues from a closely matched human antibody. Computer graphic modeling of the rodent monoclonal is used to identify these surface residues which are unlikely to be involved in maintaining the correct conformation of loops. These are then substituted. The method has

not been widely used. A few examples have been described, although no clinical data is available as yet.

Humanized products

Over 100 humanized antibodies have been described in the scientific and patent literature. They represent a broad range of target antigens including anti-infectives, anticancer, immunosuppressor and immunomodulators for treatment of autoimmune disease. The majority have been humanized as IgG1 molecules. This has been out of choice to maximize the facility for complement-dependent killing and Fc-mediated cytotoxicity. In cases where blocking of target antigen alone is preferred and to reduce binding to Fc receptors on non-target cells, as with CD4 or tumor necrosis factor α (TNF α) targets, IgG4 or IgG1 mutants defective in FcR binding have been produced.

Preclinical and clinical studies with humanized antibodies

Table 1 is a representative list of humanized antibodies advanced in preclinical and clinical studies and Table 2 describes their general properties *in vivo*. Preclinical studies in monkeys have shown no toxicity, extended half-lives and little host immune response. Clinical studies also suggest that humanization has overcome the major clinical problems of rodent antibodies. The inclusion of human antibody constant regions has entirely restored effector function activity. Humanized antibodies have serum half-lives of the order one would expect for human antibodies against the same target antigens. Greatly reduced HAMA response has been observed, although anti-idiotypic responses are sometimes elicited.

As with any drug, therapeutic success requires the target to be carefully chosen. In particular, where the target is a normal body component, the therapeutic

threshold over toxicity due to blockage of normal biological function must be carefully defined. Two of the early humanized antibodies CAMPATH-1H and Anti-Tac did not show efficacy in phase II trials for bone marrow transplantation and graft-versus-host disease, respectively, but are being evaluated for other applications. The clinical effectiveness of humanized antibodies will undoubtedly vary widely but one can be optimistic that humanized antibodies will provide a new class of therapeutics in the coming years.

HUMORAL IMMUNITY

Claudia Berek, Deutsches Rheuma Forschungs Zentrum, Berlin, Germany

When a foreign substance enters the body, an immunological reaction may occur. Traditionally, immune responses are divided into two different types of reaction: a cell-mediated and a humoral immune response. However, for both types of responses, immunocompetent cells called *lymphocytes* are of major importance. The term humoral response derives from the fact that the antibodies which mediate it are dissolved in body fluids (humor) such as blood, tears, sweat, etc. These antibodies – characteristic of the humoral immune response – are secreted by a subset of lymphocytes called B cells. The other major subset of lymphocytes, T cells, contribute to the humoral response and are largely responsible for cell-mediated immunity.

The first antibodies made by a B cell are not secreted. They are inserted into the plasma membrane, where they serve as receptors for foreign substances. As predicted by the clonal selection theory,

all of the antibody molecules made by an individual B cell have the same antigen-binding site. Once a B cell has bound antigen, it is stimulated to proliferate. Activated B cells will develop into terminal effector cells, called plasma cells and, through a complicated and poorly understood series of events, into memory cells. Plasma cells secrete large amounts of antibody molecules into the blood plasma and the tissue fluid. Memory cells provide long-term protection. They enable an individual who has been exposed to an antigen once to respond more rapidly and efficiently to a second encounter.

Immunoglobulins (Igs) are present throughout the vertebrate kingdom but have not been identified in invertebrates. A basic feature, maintained during evolution, is the four-chain structure, comprising two light (L) and two heavy (H) chains (**Figure 1**). The amino-terminal portion of the H and L chains is the variable, and the carboxy portion the constant

Figure 1 Basic four-chain structure of immunoglobulin.

part of the molecule. The variable regions of H and L chains together form the antigen-binding site.

During the evolution of vertebrates, various mechanisms have evolved to allow the individual to produce an enormous number of antibody molecules with different variable regions and hence of different specificity. The potential repertoire of the mouse could be as high as 10^{10} different molecules.

The L chain constant regions exist in two distinct forms, giving rise to two distinct types of L chains known as κ and λ . The constant region of the H chains define the antibody class and is responsible for a variety of characteristic effector functions. In higher vertebrates there are five different types of H chain constant regions and hence five different classes of antibodies: IgM, IgG, IgA, IgD and IgE. In addition, there are a number of subclasses of IgG. The function of the different H chain classes is shown in Table 1.

During the development of B cells, one particular combination of H and L chain variable regions will be found associated with antibodies of different immunoglobulin classes. Therefore, the same specificity can be attached to functionally different constant regions.

Table 1 Effector function of different immunoglobulin classes

IgM	Early immune response; first class of antibody to appear in serum; complement fixation; stimulation of ingestion by phagocytes
IgG	Produced later in the immune response; major antibody in serum; complement fixation; stimulation of ingestion by phagocytes; placental transfer
IgA	Major class of antibody in external secretions; protects epithelial surfaces from invasion by microorganisms
IgE	Involved in reactions to allergens; triggers inflammation through stimulation of mast cells; induced by parasitic infections
IgD	Very little secreted; function not clear
-	-

Cellular and molecular basis of the humoral immune response

An antigen, e.g. a bacterium, virus or toxin, may stimulate the differentiation of B cells into plasma cells. There are two different pathways by which B cells can be activated to differentiate into plasma cells:

1. *T-independent response.* In this case, B cells will be activated even in the absence of T cells. There are two types of T-independent antigens: T1-1 antigens activate a proportion of B cells polyclonally, irrespective of the specificity of their antigen receptor. T1-2 antigens are normally large polymeric molecules with repeating antigenic determinants (e.g. polysaccharides with identical subunits), such as the capsular antigens of microbial organisms, which directly cross-link the B-cell antigen receptor.
2. *T-dependent response.* In this case, the response depends on both T and B cells recognizing the antigen. In such a response, the differentiation of the B cells depends on the interaction with T cells.

In an immune response which is independent of T cells, the antibodies produced are mainly of the IgM class. Even in a T-dependent response, B cells first develop into plasma cells which secrete IgM antibodies. However, in a T-dependent response, factors secreted by the T cells (cytokines) will direct B cells to switch to other Ig classes: IgG, IgA or IgE. Consequently the B cell product (antibody) will acquire the biological properties characteristic of each Ig class.

Maturation of the immune response

In a T-dependent response, the affinity of the secreted antibody for the antigen increases. This is referred to as affinity maturation of the immune response. Analysis of the primary structure of antibody molecules has shown that the increase in antibody affinity correlates with an accumulation of somatic mutations in the variable region of the antibody molecule. Antigen-activated B cells migrate into the primary follicles of the lymphoid organs. There, proliferation of B cells leads to the formation of germinal centers. During clonal expansion in the germinal centers the hypermutation mechanism which is activated diversifies the B cell repertoire. Intracloal diversity is generated by nucleotide substitutions specifically introduced into the H and L chain variable region genes. Antigen presented on Follicular Dendritic Cells (FDC) permits selection of the few high-affinity variants which may then differentiate into memory and plasma cells. In this way through hypermutation and selection an affinity maturation

of the immune response is ensured and the affinity of the secondary response antibodies is generally higher than that of the primary response antibodies. The immune system 'learns' from the first contact with an antigen, so that at a second encounter the humoral immune response will not only be of greater quantity but also of greater quality.

Function of the humoral immune response

Among the major functions of a humoral immune response are:

1. Neutralization of either toxin or virus.
2. Agglutination of bacteria and other pathogens followed by phagocytosis.
3. Activation of the complement system via antigen-antibody complexes, which leads to cell death through lysis or phagocytosis or to acute inflammatory processes.
4. Antibody-dependent cell mediated cytotoxicity (ADCC).
5. Protection from microorganisms by preventing their attachment to epithelial cells.

Antigen-antibody complexes activate complement

When IgM and most subclasses of IgG (human: IgG3 $\geq$ IgG1 $\gg$ IgG2, mouse: all IgG subclasses except IgG1) bind to foreign antigens, they may trigger the classical complement pathway. Three major effector mechanisms are activated by complement:

1. *Lytic pathway of complement.* Following complement activation by an antigen-antibody complex, a cascade of events is initiated; this culminates in the lysis of the attacked cells.
2. *Immune adherence and phagocytosis.* Phagocytic cells have specific receptors for the complement cleavage product C3b on their surface, which promotes the process of immune adherence and phagocytosis of microorganisms.
3. *Acute inflammatory reaction.* Along the reaction sequence of the complement system, cleavage products of complement proteins are generated and released. These cleavage products have chemotactic activity and attract large numbers of phagocytic polymorphonuclear leukocytes, which lead to the development of an acute local inflammatory reaction.

Phagocytic response

The principal phagocytes of the blood – the granulocytes – can bind and ingest foreign particles,

especially those which have been 'opsonized' by binding antibodies and/or complement. Human antibodies of the subclasses IgG1 or IgG3 directly act as opsonins, whereas antibodies of the IgM class only enhance phagocytosis in the presence of complement. In the first step, the variable region of the antibody molecule binds specifically to the surface of the pathogen or parasite. The constant region of the IgG H chains will then attach to specific receptors (Fc receptor, Fc γ R) on the surface of the phagocyte. In the case of antibodies of the IgM class, immune adherence takes place via an antibody-complement complex. A cleavage product of complement (C3b) binds to specific receptors on the phagocytic cell (CR1, CR2), thus completing a bridge between bacteria and phagocytic cells. The microorganisms can then be phagocytosed. Similar mechanisms apply to tissue phagocytes (e.g. macrophages, Kupffer cells, microglia, etc.).

Antibody-dependent cellular cytotoxicity

Various cell types, which express Fc receptors, including natural killer cells, are capable of lysing target cells. However, lysis will occur only when the target cell is precoated with specific antibody. Natural killer cells express a low affinity receptor (Fc receptor, Fc γ RIII or CD16) with specificity for determinants in the constant part of the IgG H chain. Recognition of the IgG bound to the target cell through the Fc receptor will signal the cytolytic pathway. Eosinophils express Fc receptors with specificity for determinants in the constant part of the IgE H chain. In this way parasites, such as helminths, which induce an IgE response, can be killed by eosinophils.

Protective function of IgA antibodies

Immunoglobulins are found not only in serum but also in various body secretions such as saliva, sweat, milk, tears, and respiratory and intestinal secretions. Binding of an IgA to the Poly Ig receptor enables IgA antibodies to be transported across mucosal tissues into secretions. Hence IgA is the predominant immunoglobulin class in the external secretions of most species. By combining with microorganisms, it prevents their attachment to mucosal or epithelial surfaces and thus inhibits invasion of the body.

Aberrant humoral responses

Self-directed humoral immunity

Immunological tolerance is the process that normally prevents lymphocytes from reacting with self antigens. Under certain circumstances, immunological tolerance breaks down and autoimmune disease

results. Humoral antibodies to self antigens on cell surfaces can lead to cell death by direct complement-mediated cell lysis, by ADCC or by opsonization. Antibodies directed against hormones or against cell surface receptors may interfere with cell function. One such example is the autoimmune disease myasthenia gravis, where antibodies react with the receptor for acetylcholine at the neuromuscular junction.

In addition in autoimmune diseases such as systemic lupus erythematosus, the continued production of autoantibody to self antigens leads to the formation of large amounts of immune complexes which are deposited in various tissues. These complexes activate the complement cascade, which leads to acute local inflammation at the site of deposition. Various serious diseases such as vasculitis, nephritis, endocarditis or rheumatoid arthritis may be the result.

Immediate-type hypersensitivity reaction

The immediate-type reaction, in contrast to delayed-type hypersensitivity, is always a humoral immune response. In an organism sensitized by a given allergen, a new contact with the allergen will lead to an immediate reaction. The localization of the allergen by specific antibodies of the IgE class (reagin) on to mast cells leads to the activation of the mast cells. The resulting degranulation of the mast cells releases mediators such as histamine, serotonin, heparin and proteolytic enzymes. The result is an immediate inflammation reaction which may range from a local skin reaction to a potentially lethal anaphylactic shock.

Manipulated responses

Passive immunization

Protection can be transferred passively by injection of specific antibodies. This effect of humoral immune protection was first realized by Kitasato and Behring who treated diphtheria in children by using sera of animals immunized with the toxins. The duration of protection depends on the amount of antibody injected and on the half-life of the class of immunoglobulins introduced.

One important application for passive immunization is the rhesus (Rh) prophylaxis, whereby Rh-negative mothers are injected with anti-Rh antibodies *post partum*. This prevents the activation of the mother's immune system by Rh-positive blood cells of the newborn child.

A natural passive immunization occurs during pregnancy when IgG antibodies are transferred through the placenta into the fetus, thus providing humoral immune protection. A passive immunization is also given by antibodies of the IgA class in milk and colostrum, which may protect the gastrointestinal tract of the newborn.

Active immunization

The immune system can be directly stimulated by injection of an antigen into the organism. Such an active immunization is referred to as vaccination. In a humoral response, B cells will be activated and differentiate into plasma cells and memory cells. Thus long-term protection will be achieved. The enormous power of vaccination can be seen in the fact that by this means diseases such as polio or diphtheria can be controlled or even, in favorable circumstances, eradicated (smallpox).

HYBRIDOMAS, B CELL

John F Kearney, Division of Developmental and Clinical Immunology, Department of Microbiology and The Comprehensive Cancer Center, University of Alabama at Birmingham, Birmingham, Alabama, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Historical background

Hybridoma production has as its background the joint application of two independently derived biological research tools. The first of these was the availability of induced monoclonal plasmacytomas in the mouse, for which Potter is primarily responsible. The availability of these lines and their ability to be transplanted *in vivo* and their subsequent adaptation to *in vitro* culture and fusion with normal B cells are described below. The second earlier-derived technology was that of cell fusion in which two somatic cells could be fused, resulting in the production of hybrid cells. The frequency of isolation of hybrid lines was then greatly facilitated by the use of selective media described by Littlefield, coupled with advances in the use of new fusion-inducing agents such as Sendai virus, lysolecithin and polyethylene glycol.

The origins of monoclonal antibody-producing hybridomas sprang from attempts to study immunoglobulin (Ig) gene expression and regulation in plasmacytoma cells. First, when two immunoglobulin-producing plasmacytomas were fused, both sets of immunoglobulin light and heavy chains continued to be expressed by the hybrid cells, resulting in 1) formation of hybrid molecules, 2) the failure of new immunoglobulin chains to be produced, and 3) that when a variant plasmacytoma that no longer expressed either of the wild-type light or heavy immunoglobulin chains was fused with an immunoglobulin-producing line, the nonproducer did not switch off immunoglobulin production by the other parental cell but continued to support the production of immunoglobulin from the other parent.

General aspects of hybridoma production

The immune system is capable of mounting an immune response to an almost limitless number of different antigens. Within the antibody response to each simple or complex antigen, many clones with differing specificities, affinity and avidity can be activated to antibody production by the multiple antigenic determinants (epitopes) of an immunogen. Few, if any, true monoclonal antibody responses occur in responses to antigens, although in some

responses a very restricted number of B cells clones may be engaged in antibody production.

In 1976 Köhler and Milstein described details of a powerful method in which B cells secreting antibody of one specificity could be fused with a continuously growing plasmacytoma. Clones of hybrid cells derived in this way, which express the immunoglobulin genes from both the normal antibody-forming B cell and the plasmacytoma, inherit the potential for unlimited growth from the continuously growing plasmacytoma parent and the genetic material determining a given antibody specificity from both antibody-secreting parents. The term hybridoma was coined to describe the fusion product of a normal antibody-forming cell with a plasmacytoma; for this important scientific advance Köhler and Milstein received the Nobel Prize for Medicine or Physiology in 1984.

As illustrated in **Figure 1**, when an animal is immunized with a given antigen, the antibody products secreted by the array of B cell clones triggered by the various epitopes on the immunizing antigen subsequently appear as a heterogeneous mixture in the immune serum. However, by constructing hybridomas from a member of each epitope-specific clone and then cloning these hybrids, monoclonal antibodies can be separated from other monoclonals with specificities toward the same or other epitopes on the same antigen. It is then possible to isolate a number of monoclonal antibodies specific for different epitopes on the same molecule or immunogen. Such highly specific antibodies can be used to probe the structure and function of different parts of molecules and various cell types without need for immunoadsorptions, and at the same time a virtually unlimited supply of antibody can be obtained that is constant in its specificity and affinity over time.

Hypoxanthine, aminopterin, thymidine (HAT) metabolism and selection procedures

In fusion procedures between two cell populations the frequency of fusion is low (1 per 10^4 of the lymphoid cells). Therefore, in order to select against the neoplastic plasmacytoma or lymphoma lines used in B cell hybridoma formation, a strategy must be employed to kill the nonfused cells because they have the potential for continuous *in vitro* growth and would eventually overgrow the minority hybrid cells.

Figure 1 Comparison of conventional anti-sera production *in vitro*. By cloning the B cell-derived hybridoma lines, the antibody (Ab) products of each individual clone can be separated and propagated indefinitely. In this way individual epitopes (Ep) of an antigen (Ag) can be analyzed because of the monospecificity of monoclonal antibodies.

The method most commonly in use was developed by Littlefield and relies on the initial isolation of mutant plasmacytomas (Figure 2) lacking the enzymes responsible for the reincorporation of purines and pyrimidines into DNA and RNA (Table 1). Cells that have mutations resulting in the functional absence of these enzymes will be the only cells to survive when these toxic base analogs are incorporated into the growth media. Thymidine kinase-negative (TK⁻) or hypoxanthine guanine phosphoribosyl transferase-negative (HGPRT⁻) plasmacytoma cells can be selected, cloned and isolated in this way.

Once such mutant lines have been isolated it is

Table 1 Toxic base analogs and associated enzyme deficiency

Analog	Enzyme deficiency
6-Thioguanine (TG)	Hypoxanthine guanine phosphoribosyl transferase
8-Azaguanine (AG)	Hypoxanthine guanine phosphoribosyl transferase
Bromodeoxyuridine	Thymidine kinase

possible to select against the growth of these enzyme-deficient plasmacytoma lines by forcing them to use the salvage pathway for DNA synthesis. This is achieved by using the folic acid analog, aminopterin, which blocks the normal pathway for purine and pyrimidine synthesis, as shown in Figure 2. The plasmacytoma is then forced to use the salvage pathway but because the mutants lack one of the necessary enzymes they do not survive in the HAT medium.

The genetic defect in such mutant plasmacytoma lines that results in the absence of a functional salvage pathway is of little importance during growth of these cells in normal medium because these enzymes are involved *only* in salvage pathways synthesis, and under normal conditions this alternative route of nucleotide synthesis is unnecessary. Spleen cells, on the other hand, can synthesize a complete set of salvage pathway enzymes and, when fused to the HGPRT⁻ or TK⁻ plasmacytoma cells during hybrid formation, enable the hybrid cells to produce sufficient HGPRT or TK for the fused cells to survive in the HT medium which contains hypoxanthine and thymidine. In this way, nonfused plasmacytoma cells are killed, while the hybrids resulting from fusions with normal cells continue to grow. In contrast,

Figure 2 HAT medium metabolism: principal and salvage pathways involved in the synthesis of DNA. The toxic base analog described in Table 1 can be incorporated by the salvage pathways. In mutant lines lacking either TK or HGPRT such bases cannot be incorporated and are therefore nontoxic for such mutant lines and these cells live. Growth of these mutants will not occur when aminopterin is used to block the principal pathway of synthesis of purines and pyrimidines because both enzymes are necessary. Only those hybrid cells that contain normal levels of HGPRT from the nonmutant parental B cell partner will be able to live in HAT medium and the remaining unfused myeloma cells die. HGPRT, hypoxanthine guanine phosphoribosyl transferase; PRPP, 5-phosphoribosyl-1-pyrophosphate; TK, thymidine kinase.

normal unfused B cells have only a limited lifespan *in vitro* because they are not transformed, do not proliferate and eventually die.

Choice of fusion partner

Since the hybridoma cells resulting from cell fusion have the capacity to continue synthesis and secretion of both sets of immunoglobulin light and heavy chains from the fusing partners, scrambled hybrid molecules can be synthesized, which may lead to a corresponding decrease in specific antibody titer and/or creation of new specificities by the combination of inappropriate light and heavy chains. This problem can be avoided by using a plasmacytoma for fusion that has lost the ability to synthesize its own immunoglobulin chains.

Practical immunization procedures

Lymphoid cells from a variety of sources including spleen and lymph nodes have been used in the formation of useful antibody-secreting hybridomas. Most foreign proteins, polysaccharides or whole cells can be administered with or without adjuvants by a variety of routes. Priming immunization is generally followed by several subsequent immunizations at various intervals. Between 1 and 2 days after the last immunization, the spleen cells are removed and fused with the chosen plasmacytoma line.

Protocols for immunizations vary considerably between investigators and depend to a large extent on the quantities and the type of antigen(s) used. The use of lymph node cells has one advantage in that a high proportion of IgG-producing hybrids is obtained. These antibodies are preferable because of the greater ease in preparation and isolation of IgG antibodies over IgM monoclonals. The preparation of hybridomas, subsequent screening, testing for specificities and production of monoclonal antibodies are illustrated in Figure 3.

Heterohybridomas

Interest in producing monoclonal antibodies from species other than mice has been high and there have been reports of the use of murine plasmacytoma cells to construct interspecies hybridomas secreting non-mouse antibodies of human, rat and rabbit origin. However, the utility of these hybridomas is limited by the rapid chromosome segregation that characteristically occurs when cells from differing species are fused. With interspecies antibody-secreting hybridomas made with mouse plasmacytomas, the human, rat and rabbit chromosomes are lost preferentially. These chromosome losses appear to be related to the degree of phylogenetic disparity between the fusing species. Factors causing this chromosome loss are not well understood but may involve preferential loss of human chromosomes derived from the slower-growing human parental cells. Other factors that may lead to chromosome loss include faulty interaction between chromosomes and spindle fibers of disparate origin resulting in preferential loss of nonmouse chromosomes.

In contrast to the difficulties involved in the use of these interspecies hybridomas for actual antibody production and isolation, this preferential segregation of one set of chromosomes has been extremely useful in determining the chromosomal location for certain structural genes. By monitoring the loss of human chromosomes by cytochemical techniques, accompanied by chromosome banding and identification, it has been possible to associate certain chromosomes with appropriate phenotypic expressions. Location of genes to particular chromosomes can then be made and in this way the human heavy chain cluster of genes has been mapped to human chromosome 14 and, by a modified method using cDNA probes on these interspecies hybrids, the assignment of the light chain and loci was located to specific mouse chromosomes.

Figure 3 Outline of steps involved in production of monoclonal antibodies.

Although attempts have been made to produce cell lines from other species that would be useful in the isolation of stable hybridomas from these same species, these attempts have been met with little practical success. Recently however plasmacytomas have been derived from rabbits transgenic for *c-myc* and *v-abl* and used to make fusion partners for B cells derived from immunized rabbits. Rabbit-rabbit antibody-producing hybridomas that are stable and appear to secrete specific antibodies have been made using this cell line.

Examples of hybridoma use

B cell diversity

Although related to the production of specific monoclonal antibodies, the ability to construct B cell hybridomas has also led to a greater understanding of the genetic mechanisms of the generation of antibody diversity. An extremely informative use of hybridomas has been in the analysis of the diversity of antibodies in immune responses.

Epitope recognition by monoclonal antibodies

As already discussed under general aspects of hybridoma production, the unique attribute of a monoclonal antibody is its ability to recognize one epitope on a complex antigenic structure. This provides a powerful tool for biological analysis of complex structures. However, monoclonal antibodies may sometimes cross-react with unrelated molecules due to sharing of three-dimensional molecular structure between different epitopes. Thus it is important that molecular identification be made not solely on reactivity with one monoclonal antibody. Other means of characterization should also be used. On the other hand, cross-reactivities may lead to the identification of important structural and biological relationships between macromolecules.

HYBRIDOMAS, T CELL

Shoichi Ozaki, Department of Medicine and Clinical Science, Kyoto University
Graduate School of Medicine, Kyoto, Japan

The experimental problems in T lymphocyte biology include the low frequency of specific T cells and the minute amount of active T cell products. These have been circumvented by the isolation and propagation of T cell lines and clones of defined specificity. Two basic strategies have been devised. The first is to clonally expand normal immune T lymphocytes by repetitive stimulations with appropriate antigens and antigen-presenting cells. The other, involving T cell hybridoma technology, is to immortalize normal T lymphocytes by fusion with continuously replicating tumor cells. Since the fusion can randomly immortalize T cells independently of their antigen specificity and genetic restriction, the resultant T cell hybridomas may represent the initial T cell repertoire with less bias than T cell clones, although there is no direct evidence for this. The advantage of the hybridoma technique over T cell cloning is the relative ease in obtaining large numbers of T cells of interest (without contamination with other types of cells) and their biologically active products. Thus, T cell hybridomas have provided us with a source of lymphokines and other regulatory molecules, together with their mRNA and DNA. They have also proved useful in evaluating T cell receptors and their antigen recognition mechanism. Furthermore, some murine T cell hybridomas specific for certain autoantigens can induce autoimmune diseases after adoptive transfer.

Generation of T cell hybridomas

The methods used to generate T cell hybridomas are essentially the same as for B cell hybridomas. Antigen-specific normal T cells are fused to a T cell tumor line by means of a fusion-inducing agent. Hybrids between normal T cells and tumor cells are screened for hybridomas of interest and then cloned.

Choice of T lymphoma line

Normal T cells are fused to homologous tumor partners because of the instability in interspecies hybrids. Table 1 summarizes the murine and human T lymphoma lines that have served as the tumor partner in successful fusion experiments. The most common is the murine AKR thymoma BW5147, which has yielded hybridomas with different functions, despite its Lyt-2 phenotype, which is characteristic of a cytotoxic/suppressor T cell. Besides the ability to yield functional and stable hybridomas efficiently, the tumor lines are required to possess a drug marker that makes it easy to select hybrids of normal and tumor cells. A commonly used selective marker is sensitivity to medium containing hypoxanthine, aminopterin and thymidine (HAT). Other selection methods have also been devised (see below).

Table 1 Tumor cell lines used for fusion with T cells

Cell line	Origin	Marker	Selection
BW5147	AKR/J thymoma	HGPRT	HAT
BW1100.129.237*	[BW5147]	HGPRT	HAT
AKR-A	AKR/J thymoma	HGPRT ⁻	HAT
L5178	DBA/2 leukemia	HGPRT ⁻	HAT
EL-4.BU	C57BL/6 T lymphoma	TK	HAT
CEM-T15	Human leukemia	HGPRT	HAT
CEM-AG ^R	Human leukemia	HGPRT	HAT
CEM-T3	Human leukemia	HGPRT ⁻	HAT
CEM-6	Human leukemia	HGPRT	HAT
Jurkat-6TG-3	Human leukemia	HGPRT	HAT
Hut102-B2	Human leukemia	HGPRT	HAT
DIR11(KE37)	Human leukemia	TK ⁻	HAT
CEM	Human leukemia	—	EA
MOLT-4 or Jurkat	Human leukemia	—	Soft agar

HGPRT⁻, Deficiency of hypoxanthine-guanine-phosphoribosyl transferase (HGPRT); TK⁻, deficiency of thymidine kinase (TK); HAT, hypoxanthine, aminopterin and thymidine; EA, emetine and actinomycin D.

*This line, derived from BW5147, lacks the genes of both T cell receptor α and β chains.

Enrichment of specific T lymphocytes

Since there are very few cells specific for any one given antigen in a population of immune-lymphocytes, it is crucial to enrich those T cells prior to fusion. Antigen-specific helper T cells recognize a processed antigen in the context of class II major histocompatibility complex (MHC) molecules on antigen-presenting cells (APCs), and proliferate. Therefore, they are enriched by restimulating immune T lymphocytes with the antigen and appropriate APC. Cytotoxic T lymphocytes (CTLs) are enriched by restimulation with the specific target cells in the presence of interleukin 2. Although the nature of the cell type that actually fuses is not known, activation of the immune lymphocytes appears to select cells that are favored for the fusion. Thus, some of the procedures described above can serve to enrich cells that are not only specific for antigens but also amenable to fusion.

Cell fusion

Cells are fused by means of biological, chemical or physical methods. Among them, the chemical method, which uses polyethylene glycol (PEG) as a fusogen, is the most common.

PEG method All procedures must be done at 37°C, and the medium must contain no serum because PEG precipitates protein. First, the mixture of normal and tumor T cells is washed in serum-free medium and pelleted. Next, 50% PEG solution is added dropwise, and the mixture is gently stirred. This maximizes cell contact with PEG, resulting in many fusion products. Then, warm serum-free medium is added slowly to dilute the PEG gradually without lysing the cells. Finally, the cells are centrifuged, resuspended in medium with 10% fetal calf serum (FCS), and dispersed in 0.2 ml aliquots into 96-well plates. Successful fusion is influenced by lot-to-lot variation in PEG and FCS, requiring tedious batch testing.

Electrofusion Cell fusion can also be induced by a physical method, which uses an electric pulse. This method, compared with PEG, is highly efficient, but needs a special device. Cells are suspended in fusion buffer (0.2 mM Tris-HCl, pH 7.2, containing mannitol, CaCl₂ and MgCl₂) and transferred into a fusion chamber. The cells are brought together in a low-amplitude alternating electric field (300 V cm⁻¹ for 5 s), and then subjected twice to a high-amplitude short pulse (3000 V cm⁻¹ for 10 μs), which causes an electrical breakdown of cell membranes. Cell fusion results when the membrane breakdown occurs in areas of cell-cell contact. The cells are cultured

overnight in a 60 mm dish, and then dispersed in 0.2 ml aliquots into 96-well plates.

Selection of hybrid cells

Fusion is a random process. Fusion of a population of normal and tumor T cells results in a mixture of normal-normal, normal-tumor and tumor-tumor hybrid cells together with unfused cells. Since normal T cells have a limited growth potential, most normal-normal hybrids (and normal unfused cells) die before 2 weeks of culture. Therefore the selection methods have only to kill tumor-tumor hybrids (and unfused tumor cells) and allow normal-tumor hybrids to keep growing. The most common method is HAT selection.

HAT selection When the parental tumor cells lack an enzyme hypoxanthine guanine phosphoribosyl transferase (HGPRT) or thymidine kinase (TK), selection is accomplished by culturing the fusion mixture in HAT medium. Aminopterin blocks the *de novo* synthesis of DNA. To survive in HAT medium, cells must make DNA via the so-called salvage pathway, in which hypoxanthine and thymidine are incorporated into DNA by means of HGPRT and TK, respectively. Therefore, tumor cells lacking either of these enzymes cannot grow in HAT medium, unless they fuse with normal cells provided with the required enzymes. Thus, the only cells able to grow in HAT medium are the normal-tumor hybrids. Preparation of mutants lacking these enzymes involves first mutagenizing T cell tumor lines and then exposing them to toxic base analogs that are incorporated into DNA via the salvage pathway. The toxic agents used are 8-azaguanine (or 6-thioguanine) and bromodeoxyuridine for the mutants lacking HGPRT and TK, respectively. The drug-marked variants listed in Table 1 have been selected and isolated in this way. These cell lines, however, can possibly regain enzyme activity, resulting in revertant cells that are no longer susceptible to HAT medium. Therefore it is recommended to maintain periodically the tumor cells in the presence of the appropriate toxic base analog.

Emetine and actinomycin D selection Tumor cells are treated with emetine and actinomycin D before fusion. Emetine inhibits protein synthesis in mammalian cells at the trans-location that involves movement of mRNA along a ribosome, and actinomycin D inhibits RNA synthesis irreversibly. The tumor cells treated with these drugs therefore die of ribosomal depletion, unless they fuse with normal untreated cells and are provided with the devices required for replication. Thus, only normal-tumor

hybrids are permitted to grow. Although this method is applicable to any tumor cell line, the optimal conditions of the treatment must be carefully determined for each line. This method seems to yield hybrid cells more frequently than HAT selection (10^{-4} versus 10^{-6}).

Soft agar selection An alternative method is culturing cells in soft agar after fusion. This strategy is based on the ability of T cell hybridomas to form colonies in the soft agar, whereas neither fusion partner forms colonies. By using this selection, T cell hybridomas have been successfully established from the fusion between antigen-specific normal human T cells and HAT-resistant human T lymphoblastoid cell lines such as MOLT-4 or Jurkat.

Screening of specific hybridomas

The method of selecting a few specific hybridomas out of a great number of hybrid cultures must be fast and simple enough to allow screening of many samples, and it must be unequivocal. In principle, the methods that serve to enrich specific T cells mentioned above can also be used for selecting the antigen-specific hybridomas. Thus, antigen-specific helper hybridomas are screened by examining their lymphokine-producing capability in an antigen-specific and MHC-restricted activation. Cytotoxic hybridomas are selected by a standard CTL assay using an appropriate target.

Cloning

Cloning, the initiation of a cell line from a single progenitor, can be achieved either in soft agar, by limiting dilution, or by using a cell sorter. Cloning by limiting dilution is performed by culturing hybridoma cells in 96-well plates at <1 cell per well together with feeder cells. Even on this condition, a significant proportion of wells receive two or more cells and hence cannot initiate a true clone; therefore cloning must be repeated to ensure the homogeneity of the hybrid lines. To verify the clonality it should be demonstrated that their T cell receptors are homogeneous at the level of proteins, mRNA or genes.

Problems of T cell hybridomas

Despite the advantages mentioned above, several

experimental problems with T cell hybridomas have made them less useful than continuous T cell clones. First, T cell hybridomas, particularly human hybrids, show a greater tendency to be unstable in their function during culture. This may be due to a rapid loss of chromosomes or somatic mutations. Therefore it is essential to cryopreserve large numbers of vials of cloned hybridomas as well as to repeat recloning. Another problem to be borne in mind is that T cell hybridomas are not necessarily the faithful models of normal antigen-specific T cells. Even pairs of cloned normal T cells and T hybridoma cells derived from them (i.e. fusion products of an established T cell clone and tumor cells) show a number of differences in activation requirements, affinity, lymphokine secretion and effector functions. These differences may result from the use of T cell receptor genes of the tumor fusion partner, from different gene regulation in the hybridomas, or from differences in the screening methods for preparing them. Thus, despite the validity of T cell hybridomas as models of the corresponding T cell clones, caution must be used in such an extrapolation. To minimize such differences, parental tumor cell lines that lack T cell receptor genes have been devised (Table 1).

Cell lines are available from various sources, including the American Type Culture Collection (ATCC) [Phone 301 881 2600; Fax 301 816 4367; Internet <http://atcc.org>] and the European Collection of Animal Cell Cultures (ECACC).

HYDROSTATIC PRESSURE, EFFECT ON IMMUNE SYSTEM

Meir Shinitzky, Venkatesh Ramakrishna and Andrei Matsaev, Department of Membrane Research, The Weizmann Institute of Science, Rehovot, Israel

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

In most eukaryotic systems, thermodynamic parameters such as temperature, volume or pressure are kept constant or allowed to modulate in a well-controlled narrow range. Temperature or pressure can be used for induction of preconceived irreversible changes in constitution and structure of biological tissues, like the cell plasma membrane, which could be then applied in an *in vivo* system (e.g. vaccination). In this respect, pressure is the method of choice, as it does not involve chemical modification and is generally applied under isothermal conditions.

Pressure can operate either as a transient vector (e.g. pressure difference across a membrane) or as an intrinsic scalar (i.e. hydrostatic pressure). Biological processes related to vectorial pressure include gas equilibrium across biological membranes (e.g. oxygen-carbon dioxide exchange in the lung alveoli or cell rupture upon sudden change in pressure) and osmotic regulation of membrane transport. Hydrostatic pressure is an internal thermodynamic factor which is in equilibrium with the ambient atmospheric pressure. A change in the latter by a magnitude of ΔP is reflected in a change in the internal energy of the system by $\Delta P \cdot \Delta V$, where ΔV is the overall change in volume. When a heterogeneous system, such as a biological tissue, is subjected to external hydrostatic pressure, only the compressible elements, i.e. those where ΔV is significant, will comply with pressure. Compartments with low compressibility ($\Delta V \sim 0$) will remain practically unaffected.

Compressible compartments

Water, solutes and most soluble macromolecules are of low compressibility under hydrostatic pressures below 1000 atm. Compression of biological membranes at this range originates predominantly from intermolecular free space, which is characteristic of lipid and protein assemblies. The lipid layer in biological membranes is readily condensed by pressure. As a result, the free space between the phospholipid molecules is reduced and the lipid structure becomes more ordered and viscous with respect to the magnitude of the applied pressure. In the extreme case, the lipid can undergo a phase transition to an ordered

gel phase, which is highly dense and therefore of low compressibility. Upon decompression, the lipid layer returns practically to its initial state.

Protein assemblies and multimers also include appreciable free space which can be released under pressure. In this case, the overt effect of pressure is not gradual, as in the case of lipids, but is quite abrupt in correspondence with the pressure threshold which induces dissociation to monomers. Reduction of pressure below this threshold level will then allow the proteins to reassemble.

When hydrostatic pressure in the range of 1000–1500 atm is imposed on cells, the increase in order and microviscosity of the membrane lipids is similar in magnitude to that induced by doubling the level of membrane cholesterol. The cytoskeletal network, which is composed of microtubules and microfilaments, is almost completely dissociated to form soluble monomers. As a result, some of the membrane proteins are displaced vertically, and a part of them is shed off into the aqueous domain, due to excessive displacement and dissociation from the cytoskeletal anchorage. Most other membrane proteins aggregate nonspecifically to form segregated domains (Figure 1). When a slow decompression is allowed, the affected cellular systems readjust with respect to the ambient pressure through a series of equilibria until atmospheric pressure is attained. Along with decompression, the protein aggregates will dissociate in part, while proteins of some affinity will remain associated as the cytoskeletal boundaries are reassembled.

Another, somewhat unexpected, effect of hydrostatic pressure is on protein synthesis. Similarly to protein assemblies, complexes between various suppressors and genetic matrices can dissociate under pressure and immediately evoke protein synthesis. This process can be classified as stress induced (e.g. analogously to heat shock protein (hsp) synthesis). Some of the pressure-induced proteins presumably take part in the surface presentation of antigens, as shown in Figure 2, and thus contribute to the apparent immunogenicity. The modulation in surface antigens which follow such a process, in particular the overt augmentation of major histocompatibility complex (MHC) presentation, is a combination of lateral and vertical displacements, presented in Figure 1,

Figure 1 Structural changes on the cell surface induced by high hydrostatic pressure. Four schematic membrane domains ('unit membranes'), separated by cytoskeletal boundaries, are displayed. Under high pressure (as exemplified by 1500 atm), the boundaries are fully disintegrated, and the lipid regions become highly ordered and dense (not shown). Some proteins are then shed off to the outer space (4), while most other proteins are aggregating into segregated domains. Gradual release of pressure will allow the lipids to regain their fluid nature and protein aggregates to dissociate, except for proteins with some affinity (presented in the figure as proteins of the same kind) which will remain associated. The cytoskeletal boundaries which reassemble with release of pressure will maintain the new topology as long as membrane biogenesis has not been effective (up to about 24 h). Chemical cross-linking can fix the new protein topology in pressurized cells. This is the basis of the technology of combining hydrostatic pressure and cross-linking (PCL) for the preparation of tumor vaccines.

Figure 2 Pressure induction of protein synthesis leading to increased immunogenicity. Synthesis of numerous proteins is enhanced under hydrostatic pressure. Among them is HSP96, which on its own can carry processed antigenic peptides and can presumably dock on the cell surface. In parallel, the processed antigens carried by HSP can be loaded on the MHC molecules in the endoplasmic reticulum to be further transported to the cell surface.

and pressure-induced protein synthesis, described in Figure 2.

Application of hydrostatic pressure of the above range in a biological system *in vitro* (e.g. cells in suspension) can be carried out by placing the sample in a cylindrical metal chamber equipped with a sliding metal shaft. After filling the space with water or buffer, the chamber is closed, excluding air space or bubbles. Pressure is then applied gradually and maintained at the level where the expected modifications in cell structure take place. Upon slow release

of pressure back to the atmospheric level, the treated sample is collected and applied in further experiments.

Only limited information on the effect of hydrostatic pressure on immune function is currently available. It is discussed in the following sections under two distinct conditions – while under pressure and after return to atmospheric pressure.

Immune function under pressure

Physiologically relevant hyperbaric conditions, in general, refer to deep water or fast motion, as in an aircraft or spacecraft. In both, the ambient pressure does not exceed 10 atm. Rotational motion such as in an ultracentrifuge can build hydrostatic pressure of about 100 atm. However, under such pressures, the changes in structure and density in the compressible compartments remain by and large insignificant and the observed effects in function can only be attributed to a dynamic factor.

Formally, this could be related to ΔV in a transition state of a molecular process, which in principle can become significant even upon small changes in pressure. Technically, however, the resolution of such specific pressure-sensitive dynamic events in the framework of physiologic processes is complicated. The majority of the observed physiologic changes induced by pressure at this range can, as a first approximation, be attributed to indirect effects caused by changes in blood flow or oxygen level ('hyperbaric oxygenation').

It should be stressed that when a viable biological tissue, or even a whole animal, is kept under hyperbaric conditions for sufficient time (e.g. several days), processes of homeostasis will rectify the affected functions with respect to the ambient pressure (i.e. adaptation). In such cases, upon release of pressure, these functional aberrations will appear again and eventually be rectified by the same homeostatic mechanisms (readaptation).

The scarce experimental results on immune function under hyperbaric conditions of about 10 atm indicate an overt immune suppression, most of which might be attributed to hyperbaric oxygenation. Practically, a full recovery in immune function has been observed shortly after return to the ambient pressure.

As shown in **Figure 1**, cells under high hydrostatic pressure of about 1000 atm undergo massive topological changes. Despite the fact that such high pressure is far beyond any physiologically relevant scale, cells can apparently tolerate pressures of such magnitudes for a few hours, and occasionally even longer. Immune or other physiologic functions under such high pressures have not been reported, but it is very likely that, owing to the massive alterations in structure and dynamics, virtually all biological functions will be markedly suppressed, if not completely abolished. Merely the considerable decrease in the membrane lipid fluidity under such pressures is expected to reduce the overt function of immune cells severalfold, as can be extrapolated from the analogous

effect of decrease in membrane fluidity by cholesterol, which markedly suppresses immune function.

Pressure-augmented immunogenicity

Intact cells subjected to high hydrostatic pressure (above 1000 atm) for up to 1 h and then returned to atmospheric pressure, in general retain viability. For fixation of the transient surface topology in the pressure-treated cells, chemical cross-linking of the pressurized cells with a special impermeant reagent like 2'3'-adenosine dialdehyde (AdA) is effective, especially when plasma membranes are to be isolated and used as immunogens.

Pressurized tumor cells, as well as pressurized autoimmune cells, were both demonstrated to possess a high and specific immunogenicity. Such pressure-treated cells were successfully used in pre-vaccination trials in murine models of cancer and autoimmune diseases. These observations open novel approaches for both the diagnosis and treatment of cancer and autoimmune disease, which are currently under investigation.

H-Y, THE MALE-SPECIFIC TRANSPLANTATION ANTIGEN

Elizabeth Simpson, MRC Clinical Sciences Centre, RPMS, London

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The male-specific transplantation antigen, H-Y, was first discovered in the mid-1950s when Eichwald and Silmsker exchanged skin grafts between males and females within the same inbred mouse strain. They discovered that females of some, but not all, strains could reject skin grafts from males of the same (syngeneic) strain. In contrast, male-to-male, female-to-female and female-to-male grafts within the same strain were never rejected. Snell, because of his interest at the time in other minor transplantation antigens, interpreted these data as implying the presence of a minor H antigen gene on the Y chromosome, and it was Snell who named it H-Y, for histocompatibility (= transplantation) antigen on the Y chromosome. H-Y was a weak transplantation antigen in comparison with those of the major histocompatibility complex (MHC), H-2 in mice: it was therefore used by Billingham and his colleagues to explore tolerance induction during the neonatal period, following their classic work on neonatal tolerance induction across H-2 barriers. It proved much easier to induce tolerance to H-Y than H-2: fewer cells were needed in the tolerance-inducing inoculum, which could be given up to 10 days after birth.

***In vivo* responses to H-Y**

The fact that females of some but not all strains of mice rejected syngeneic male grafts suggested that there were genetic factors controlling the ability to mount an *in vivo* immune response to H-Y. These were explored in the early 1970s by Bailey, who found that genes of the MHC were the most important of the immune response (Ir) genes and, in particular, mice of the H-2^b haplotype, regardless of other genetic differences, were able to reject syngeneic male grafts, whereas very few non-H-2^b could do so. The H-2 genes controlling H-Y graft rejection were mapped toward the K end of the H-2 region by Bailey and subsequently, in 1978, into the class II region by Hurme and colleagues. The nature of non-responsiveness was explored from a different angle by Silvers in the early 1970s. He established that failure to respond was not due to the absence of the antigen in non-responder strains, that responsiveness was dominant in F1 hybrids between a responder and non-responder strains, and he found no evidence for allelism in H-Y. These findings have subsequently

been confirmed and extended by others, including those investigating *in vitro* T cell responses to H-Y.

***In vitro* responses to H-Y**

The skin graft rejection responses to H-Y implied cell-mediated immunity, as defined by Medawar for graft rejection responses by recipients of grafts from donors with much broader genetic disparities. However, the concomitant humoral immune responses, with the production of antibodies at least to MHC antigens, made the search for antibodies to H-Y a sensible one; had they been successful, the molecular characterization of the H-Y antigen would have been straightforward. However, despite a promising start by Goldberg and her colleagues, who in 1971 found in the serum of female mice immunized with male tissues factors which preferentially bound to sperm cells and epidermal cells from male mice, these proved to be of very low titer and difficult to work with. No satisfactory monoclonal antibodies (mAbs) specific for H-Y were produced from the time when mAbs were shown to be so useful for molecules which would otherwise never have been characterized. In retrospect, the logic which equated the specificity of the low titer, sperm-binding antibodies with the previously described male-specific minor transplantation antigen, H-Y, could be faulted but, at that time, with no other characteristics attributed to the H-Y chromosome (but see below) it was understandable.

Shortly after her work with putatively H-Y specific antibodies, Goldberg published the first paper showing that H-Y-specific cytotoxic T cells could be detected *in vitro* in the draining lymph nodes of female H-2^b mice that had recently rejected a syngeneic male graft. Subsequently, the level of cytotoxicity found in such populations was shown by Simpson and colleagues to be raised following a secondary mixed lymphocyte culture (MLC) step after the *in vivo* immunization, and they were the first to demonstrate that such H-Y-specific T cells were MHC restricted, in the same way that Bevan showed for cytotoxic T cells specific for other minor transplantation antigens. The ability to generate H-Y-specific T cells restricted by some but not all MHC molecules proved to be a very powerful way of analyzing the manner in which MHC genes acted as Ir genes and

establishing that the Ir gene products were in fact the MHC molecules. The work with H-Y established that not only were MHC class II molecules the Ir gene products, as was clear from the pioneering Ir gene work of McDevitt and Benaceraff with T helper cell and antibody responses to synthetic polymers, but the MHC class I molecules were the products of Ir genes controlling cytotoxic class I-restricted (CD8) T cells. In humans, CD8⁺ cytotoxic T cell clones specific for H-Y and restricted by HLA class I molecules have been isolated by Goulmy from female patients rejecting tissues and organs from HLA-matched males.

MHC and non-MHC Ir genes controlling T cell responses to H-Y

The identification of those alleles of MHC class I and II molecules that were permissive for T cell recognition of H-Y established the basis for understanding why some but not all strains could respond to H-Y by skin graft rejection and/or *in vitro* cytotoxic and proliferative responses. However, it was clear that genetic factors other than those of the MHC were also involved. Skin graft rejection appeared to require only a permissive H-2^b class II gene and, with few exceptions, only female mice with this allele could reject primary syngeneic male skin grafts. On the other hand, the generation of cytotoxic T cells *in vitro* following *in vivo* immunization, required a combination of a permissive class II and a permissive class I allele – the first to excite a CD4⁺ cell specific for H-Y, which would then provide help for the clonal expansion of H-Y specific, class I-restricted, CD8⁺ cytotoxic cells. The relative efficiency of different class II alleles in providing this help also depended on the route of *in vivo* immunization. For female mice with the H-2-A^b allele, any route would serve, i.e. following skin grafting or intraperitoneal or footpad injection of syngeneic male cells; for mice of the other commonly encountered H-2 haplotypes, H-2^{k,d,s,q}, the only way to generate cytotoxic T cell responses was by footpad priming. However, among mice of each of these latter haplotypes, there was variation in the ability to respond; some H-2^k strains did, others did not, and examples of responders and non-responder strains were found for each haplotype. This result implied that other, non-MHC Ir genes were also able to influence the response and a number of these have been chromosomally located, although not yet characterized at the molecular level. Similarly acting non-MHC Ir genes have been reported in controlling immune responses to a number of other antigens – some extrinsic, like hen egg lysozyme (HEL) and some, like H-Y, intrinsic, such

as autoantigens. For example, in type I insulin-dependent diabetes mellitus (IDDM) in humans as in the genetically predisposed inbred mouse strain NOD (non-obese-diabetic), in addition to the key MHC-associated Ir genes, there are non-MHC Ir genes. The manner in which they operate is at the moment unclear but, by analogy with the T cell receptor (TCR) repertoire selection function of self-ligands associated with self-MHC molecules, it seems possible that some might interact with MHC molecules, so that the self-non-MHC ligand/MHC molecule complex could positively or negatively select the TCR repertoire and hence affect the ability to respond to antigens.

The putative role of H-Y in sex determination

In the mid-1970s, following the reports of MHC-restricted T cell recognition of H-Y, and the possibility of there being antibodies which might detect the same antigen (see section entitled *in vitro* responses to H-Y), Ohno put forward the very attractive hypothesis that the sex-determining role of H-Y was mediated by H-Y that was viewed as a molecule associated with MHC molecules in the cell membrane and therefore well placed to provide cell-cell signaling during embryogenesis. Since few other genes had been mapped to the Y chromosome, the presence of which was clearly crucial for male sex determination in mammals, a hypothesis which equated the transplantation antigen H-Y, the serological entity then called by the same name and testis-determining function, was one which caught the imagination and inspired a number of experiments, some better controlled than others, to prove or disprove it. The denouement has been that both in mouse and man, using H-Y-specific MHC-restricted T cell clones to H-Y type cells from individuals carrying various deletions and mutations of the Y chromosome, that part of the Y chromosome which carries the H-Y gene is separable from that which carries the testis-determining gene, so that they cannot be one and the same. In man, the testis-determining gene (SRY) is on Yp, the short arm, while the H-Y antigen gene (HYA) is on the long arm, Yq. In mouse, the testis-determining gene (Sry) and the H-Y antigen gene (Hya) are closely linked on the short arm but have been separated in the mutant Sxr^b (Hya absent, Sry present) and by the several Y chromosome mutations which have lost Sry function but retained Hya. The serological reagents are not sufficiently discriminatory for them to have been used in the HYA/Hya chromosomal mapping analyses, for while they can distinguish a group of positive

individuals (males) from a negative one (females) in terms of an average measurement for each group, individuals cannot be confidently assigned to either.

Molecular identification of H-Y genes and peptide epitopes

The work on deleted and mutant Y chromosomes which separated Hya/HYA from other Y chromosome genes provided detailed mapping information which has led to the positional cloning of the genes and the identification of several H-Y epitopes in mouse and one in humans. New Y chromosome genes have also been discovered during the course of these studies and it has transpired that different H-Y peptide epitopes are derived from several linked genes, making Hya, like the loci encoding other minor transplantation antigens (see section on Minor transplantation antigens), a gene complex rather than a single gene. The first H-Y epitope to be characterized molecularly was discovered following expression cloning using H-Y-specific T cells to detect the presence of the epitope on cells transfected with DNA containing the relevant gene. The H-Y epitope associated with H-2K^k (H-Y/K^k) was identified as TENS^gKDI, the product of one of the 3' exons of the Smcy gene. The human H-Y epitope (H-Y/HLA-B7) is the peptide SPSVDKARAEL, a product of the homologous human gene, SMCY. This was deduced following the alternative approach of peptide elution coupled with microcapillary liquid chromatography and electrospray ionisation mass spectroscopy, and comparing peptide sequence with the known DNA sequence of the SMCY gene. The mouse H-YD^k epitope is also a product of the Smcy gene, being derived from one of the 5' exons, but an H-Y/D^b epitope, WMHHNMDLI, is encoded by a separate but adjacent gene, Uty. Smcy and Uty have X chromosome homologs, Smcx and Utx, which escape X inactivation; X and Y copies of both genes are ubiquitously transcribed, suggesting that two copies may be needed for function, which is currently unknown, but from their sequence the products could be DNA- or protein-binding proteins, and be involved in transcription. Perhaps unsurprisingly the H-Y epitopes, which are the basis for male-specific transplantation rejection responses, are derived from sequences at which the X and the Y homologs diverge.

Summary

Forty years ago, H-Y was defined as a minor transplantation antigen. Immune responses to it were

studied first *in vivo* and then in great detail *in vitro*, thereby contributing an understanding of the relationship between MHC restriction and MHC Ir gene function. The non-MHC Ir gene control of cytotoxic T cell responses to H-Y has provided a model for exploring non-MHC Ir gene control of T cell responses to other antigens, including autoantigens. Immune responses to H-Y have also allowed the exploration of an intriguing hypothesis about mammalian sex determination and have contributed to the chromosomal localization of genes on the sparsely populated Y chromosome. This in turn has led to the identification of genes encoding H-Y peptide epitopes, following expression cloning and peptide elution approaches. Reverse genetics has thus provided a route to characterizing molecules, or fragments thereof, recognized well by T cells but poorly if at all by antibodies.

HYPERGAMMAGLOBULINEMIA

Philip R Greipp, Divisions of Hematology and Hematopathology, Mayo Clinic, Rochester, Minnesota, USA

Hypergammaglobulinemia results from an overproduction of immunoglobulin by plasma cells, most commonly including an increase in plasma cells in the bone marrow. The plasma cell increase and the associated increase in immunoglobulin may be polyclonal or monoclonal. In polyclonal hypergammaglobulinemia, nonneoplastic plasma cells increase in number in response to an antigenic stimulus such as infection, inflammation or a neoplasm. Monoclonal increases are not dependent on such a stimulus, but rather reflect a neoplastic increase in a single clone of plasma cells. Hypergammaglobulinemic disorders are recognized clinically when a physician orders a serum protein electrophoresis during a general medical examination, or when looking for a specific disorder.

Recognition

Suspicion of an underlying infectious, inflammatory or neoplastic disorder triggers a physician to order a serum protein electrophoresis. This is a simple screening technique commonly used in clinical medicine that displays serum proteins by their electric charge (Figure 1). Media include cellulose acetate and agarose. Separate bands are seen for albumin, alpha-1 globulin, alpha-2 globulin, beta and gamma globulin. Polyclonal or monoclonal increases may be detected when the electrophoretic bands are scanned. Capillary electrophoresis gives better resolution of separate bands. When the increase is polyclonal it appears as a broad band and the electrophoretic tracing shows a broad-based increase reflecting heterogeneous immunoglobulins being produced by polyclonal plasma cells. This increase is usually in the gamma region but may extend to the beta region. When the increase is monoclonal, the electrophoretic band is narrow and the electrophoretic tracing shows

a narrow-based band reflecting the homogeneous electric charge of the monoclonal immunoglobulin.

Polyclonal hypergammaglobulinemia (polyclonal gammopathy)

Pathophysiology of polyclonal gammopathy

Polyclonal hypergammaglobulinemia is usually due to an underlying infectious, inflammatory or neoplastic disorder such as a carcinoma. Antigen is processed by antigen-presenting cells which activate T cells to induce proliferation of antigen-specific B cells. Under the influence of cytokines such as interleukin 6 (IL-6), these B cells differentiate into antibody-producing plasma cells. These polyclonal plasma cells increase in number in the bone marrow, gut, lymph nodes, spleen and liver. They produce electrophoretically heterogeneous immunoglobulins which are detected in the serum as a broad increase, chiefly in the gamma globulin band. The polyclonal increase in immunoglobulin reflects expansion and differentiation of plasma cells, collectively producing more than one isotype of immunoglobulin (Ig) heavy chain. Both κ and λ light chains are represented. Rarely, no underlying cause is found, and the increase is attributed to an unknown antigen exposure or defective regulation of B cell proliferation and differentiation. The increase in plasma cells and gamma globulin almost never causes symptoms. The presence of symptoms reflects the specific underlying disease.

Rarely, the polyclonal hypergammaglobulinemia may be restricted to one or more subclasses of immunoglobulin (Ig). Hyper-IgM syndrome is described in another article in the encyclopedia. Hyper-IgE, or Job's syndrome, is characterized by a polyclonal increase in IgE alone. In these patients the catabolic destruction of IgE is slowed. The primary

Figure 1 Serum protein electrophoresis. On the left is a normal pattern. Note the gamma globulin band is wide and the densitometric tracing is broad-based. On the right is a monoclonal gammopathy pattern. The gamma region contains a narrow band and the densitometric tracing shows a tall narrow 'spike'.

cause of the IgE increase is not known. Hyper-IgD syndrome has also been described. These patients may present with constitutional symptoms including fever and headaches, and they may have lymphadenopathy. Still another group of patients may have hyper-IgG syndrome. This is a familial disorder. There is no underlying infectious or inflammatory condition, and there is no evidence of an autoimmune disease or lymphatic neoplasm. The class restriction has been linked to class-specific regulatory T cell clones.

Underlying diseases causing polyclonal gammopathy

The most profound polyclonal hypergammaglobulinemia is found in chronic liver disease, rheumatoid arthritis and Sjögrens syndrome. The gamma globulin increase in Sjögrens syndrome is characteristically associated with very high levels of rheumatoid factor (IgM anti-IgG immunoglobulin). Uncommonly, serum hyperviscosity occurs, producing signs and symptoms of impairment of blood clotting and blood flow.

Known infectious causes of polyclonal hypergammaglobulinemia include parasitic infections such as malaria, schistosomiasis, strongyloidiasis and leishmaniasis, and fungal infections such as paracoccidioidomycosis and histoplasmosis (Table 1). Other causes include bacterial infections such as brucellosis, spirochete infections such as borrelia (Lyme disease), and rickettsial infections. Various viral infections may also cause polyclonal hypergammaglobulinemia. These include hepatitis, vaccinia, and varicella zoster infections.

Autoimmune disorders commonly manifest polyclonal hypergammaglobulinemia. Among these,

rheumatoid arthritis and Sjögrens syndrome cause the most profound polyclonal increase in gamma globulin. In systemic lupus erythematosus, the increase in polyclonal immunoglobulin is usually modest but many different autoantibodies may be present, such as antinuclear antibody, rheumatoid factor, cardiolipin antibodies and antibodies against red blood cells, neutrophils and platelets. The deregulated expression of IL-6 has been implicated in the polyclonal B cell activation and hypergammaglobulinemia seen in autoimmune diseases. Continuous IL-6 stimulation in mice produces hypergammaglobulinemia and mimics the chronic B cell hyperplasia of Castleman's disease, or giant lymph node hyperplasia. Increase in serum β_2 -microglobulin (the light chain of the class I major histocompatibility complex) accompanies the polyclonal hypergammaglobulinemia seen in lupus and other autoimmune disorders such as Sjögren's syndrome. A monoclonal gammopathy or B cell lymphoma may develop in patients with Castleman's disease or Sjögrens syndrome.

In common with other neoplasms, some malignant lymphomas and lymphoproliferative disorders may be associated with polyclonal hypergammaglobulinemia. Among these are non-Hodgkins and Hodgkins lymphoma and acute lymphocytic and myelogenous leukemia. While polyclonal hypergammaglobulinemia is uncommon in these conditions, it occurs in up to one-half the cases of peripheral T cell leukemia/lymphoma and chronic myelomonocytic leukemia. Polyclonal hypergammaglobulinemia is common in patients with angioimmunoblastic lymphadenopathy with dysproteinemia (AILD). The polyclonal hypergammaglobulinemia and other disease manifestations may disappear when a causative

Table 1 Causes of polyclonal gammopathy

<i>Infectious and inflammatory</i>	<i>Autoimmune</i>	<i>Neoplastic</i>	<i>Other</i>
Chronic liver disease	Rheumatoid arthritis	Metastatic carcinoma	Angioimmunoblastic
Parasitic infections	Sjögrens syndrome	Malignant lymphoma	lymphadenopathy with
Malaria	Systemic lupus	Hodgkins disease	dysproteinemia (AILD)
Schistosomiasis	erythematosus	Acute lymphocytic leukemia	Natural killer cell/large granular
Strongyloidiasis	Polymyositis	Acute myelogenous leukemia	lymphocyte syndrome
Leishmaniasis	Mixed connective tissue	Peripheral T cell	Castlemans disease
Fungal infection	disease	leukemia/lymphoma	Acquired immunodeficiency
Paracoccidioidomycosis		Chronic myelomonocytic leukemia	syndrome (AIDS)
Histoplasmosis			Benign hypergammaglobulinemic
Bacterial infection			purpura of Waldenström
Brucellosis			
Tuberculosis			
Spirochetes			
Lyme disease			
Viral infections			
Hepatitis			
Varicella zoster			
Vaccinia			
Rickettsial disease			

medication is discontinued. In most patients with AILD however, a latent T cell lymphoma is present. Patients with natural killer (NK) cell/large granular lymphocyte (LGL) syndrome have a polyclonal hypergammaglobulinemia. Another idiopathic acquired and uncommon polyclonal hypergammaglobulinemia is benign hypergammaglobulinemia purpura of Waldenström (BHPW). Patients have characteristic vascular purpura of the lower extremities. Malignant transformation in BHPW is uncommon.

Polyclonal hypergammaglobulinemia is frequently seen in disorders characterized by immune deficits. One example is the acquired immune deficiency syndrome (AIDS). In AIDS, there is a decreased CD4/CD8 T cell ratio, yet the level of polyclonal Ig is paradoxically increased. B and T lymphocytes have a decreased response to mitogen. Some AIDS patients develop monoclonal gammopathy and eventually a neoplastic process of B cells such as lymphoma or multiple myeloma.

Monoclonal hypergammaglobulinemia (monoclonal gammopathy)

Recognition of monoclonal gammopathy

Monoclonal gammopathy is recognized when the physician notes a monoclonal peak on the serum protein electrophoresis. Immunoelectrophoresis and immunofixation to identify the type of monoclonal peak reveals an IgG, IgA, IgM or rarely an IgD or IgE monoclonal protein with either κ or λ light chains. Urine electrophoresis may reveal free monoclonal light chain.

Pathophysiology of monoclonal gammopathy

In contrast to polyclonal processes where IL-6 acts as a B cell differentiating factor, in monoclonal gammopathy and myeloma IL-6 is important for myeloma cell growth. Increased serum levels of IL-6 may be found in myeloma. Serum levels of C-reactive protein, which is synthesized by the liver in response to IL-6, are also elevated. Evidence has been presented for both autocrine and paracrine IL-6-induced growth of myeloma cells. IL-6 levels are elevated in the serum of patients with active, high tumor burden disease. Soluble receptor for IL-6 acts as a cytokine agonist, enhancing the response to IL-6. Other interleukins such as IL-3 probably also play a role in sustaining myeloma cell growth. IL-6 also inhibits glucocorticoid and Fas-induced apoptosis, further contributing to myeloma cell growth.

Myeloma cells grow selectively in the marrow. Compared to B cells, myeloma cells have lost surface CD45 and CD19, and gain CD38. Normal plasma cells do not lose CD19. Myeloma cells probably home to the marrow using surface adhesion molecules which can trigger stromal cells in the marrow to release IL-6. CD56, a neural cell adhesion molecule (NCAM) not present on normal plasma cells but present on the surface of most myeloma cells, probably aids in this process. Myeloma cells produce IL-1 β which may increase the expression of surface adhesion molecules and induce stromal cells, osteoblasts and osteoclasts to produce IL-6.

Cytokines produced by myeloma cells such as IL-1 β or tumor necrosis factor α (TNF α) are osteoclast activating factors which can cause bone damage.

Table 2 Most common causes of monoclonal gammopathy

<i>Malignant</i>	<i>Premalignant</i>	<i>Other</i>
Multiple myeloma (MM)	Monoclonal gammopathy of undetermined significance (MGUS)	Amyloidosis
Solitary plasmacytoma		Heavy chain diseases
Malignant lymphoma	Smoldering multiple myeloma (SMM)	
Waldenström's macroglobulinemia		

Bone lysis is stimulated and new bone formation is inhibited. Widespread bone destruction and bone pain is commonly seen in multiple myeloma. Free light chain produced by myeloma cells (Bence Jones protein) may be toxic to the kidney and cause renal insufficiency. Patients may be predisposed to infections from *Diplococcus pneumoniae*, *Hemophilus influenzae* or other encapsulated bacteria because of the lack of a primary antibody response and hypogammaglobulinemia.

T cells may regulate the growth of myeloma cells. T suppressor cells are elevated in the stable phase of the disease. Activated suppressor T cell subsets are increased especially in poor prognosis patients. Clonal idiotype reactive T cells have been described in myeloma. Diminished CD4 and T_H1 cells in myeloma are associated with increased infection and decreased response to vaccines. Myeloma patients have increased susceptibility to herpes zoster reactivation.

B cells are decreased in patients with myeloma. Decreased CD19⁺ B cells are associated with an increased risk of infection, and shorter survival. Although B cells are decreased, pre-B cells may be increased. Whether these are malignant plasma cell precursors or abnormally regulated normal B cells requires further investigation. *Ras* oncogene is rearranged and *ras* oncogene product may be measurably elevated in myeloma cells of some patients by flow cytometry. *C-myc* oncogene is rarely rearranged but may be overexpressed.

Serum β_2 -microglobulin is often elevated in patients with myeloma. The source may be the myeloma cells themselves. Elevated serum β_2 -microglobulin is a major prognostic factor in myeloma. Other prognostic factors include elevated plasma cell labeling index (the percent of plasma cells in S phase of the cell cycle), plasmablastic morphology, elevated serum levels of IL-6, soluble IL-6 receptor, C-reactive protein, lactic dehydrogenase and thymidine kinase, or decrease in normal CD19 B cells or CD4 T cells. *Ras* mutations in myeloma cells are also associated with a poor prognosis.

Monoclonal gammopathy-associated diseases

Among the monoclonal gammopathies, the most important disease is multiple myeloma, a malignant neoplasm of plasma cells causing bone lesions, anemia, renal failure and death, often from infection (Table 2). Occurring in just 3:100 000 people per year, it increases to 40–60:100 000 per year at age 60 and causes 2% of cancer deaths. Clonal plasma cells proliferate and replace normal bone marrow. A monoclonal protein is detectable in the serum or urine in 98% of cases. The heavy chain is either IgG, IgA, IgD or IgE; IgM myeloma is rare. Light chains are often secreted in excess of heavy chains, so free light chains may be detected in the urine, so-called Bence Jones proteinuria. A total of 75% of patients will have a monoclonal peak in serum electrophoresis and 65% will have a monoclonal peak in the urine due to free light chain; in total, 98% will have a monoclonal protein detected by either immunoelectrophoresis or immunofixation. Of the remaining 2%, most have monoclonal protein detected in the marrow plasma cells.

While multiple myeloma is uncommon, its 'benign' counterpart, monoclonal gammopathy of undetermined significance (MGUS), is about fifty times more frequent. It increases with age, reaching a frequency of 3% by age 70. At 10 years after diagnosis of MGUS about 18% of patients will have developed myeloma or another serious monoclonal gammopathy-associated disease. MGUS is distinguished from myeloma by a lower amount of M protein in the serum and urine and fewer plasma cells in the marrow, usually less than 5%. Patients do not have bone lesions, renal failure or anemia. Any class of Ig may be represented. All patients with MGUS should be followed closely for the development of myeloma. Some patients with multiple myeloma do not have progressive disease. These patients are termed smoldering multiple myeloma (SMM). Distinguishing patients with SMM from those with overt myeloma may be difficult. Correct diagnosis is essential, as SMM may not require treatment for years. The plasma cell labeling index using a bromodeoxyuridine monoclonal antibody to detect plasma cells in S phase of the cell cycle is helpful in diagnosis. In SMM the labeling index is almost always <0.4%, while in overt myeloma it is often >1%.

Amyloidosis (AL) occurs when a monoclonal light chain cannot be degraded completely and the fragments of the variable region of the light chain reassemble in the form of a β -pleated sheet that stains with Congo red. They assume a characteristic 100 Å periodicity and nonbranching fibrillar appearance under the electron microscope. Organ damage

Figure 2 Macroglobulinemia is a disease in which monoclonal plasma cells in the marrow, depicted in the lower two panels, secrete a monoclonal IgM protein, shown in the upper two panels. The plasma cells are monoclonal as shown with fluoresceinated antibody to kappa light chain (lower right panel). The secreted IgM monoclonal protein is shown to be kappa light chain restricted by immunofixation (upper right panel).

Table 3 Miscellaneous monoclonal gammopathies

Lichen myxedematosus (also called papular mucinosis or scleromyxedema)
Light chain deposition disease
Cryoglobulinemia (type I and type II)
Adult acquired Fanconi syndrome
Systemic capillary leak syndrome
Acquired C1 esterase inhibitor deficiency
Cold agglutinin syndrome

reflects deposition of amyloid. The kidneys and heart, nerves, liver, gastrointestinal tract, tongue and blood vessels are prone to develop amyloid deposits. The recognition of AL and being able to distinguish it from the nonimmunoglobulin forms of secondary, familial and senile amyloid depends on the recognition of monoclonal plasma cell proliferation by immunoelectrophoresis and immunofixation of the serum and urine, and by the detection of a monoclonal increase in plasma cells in the marrow using immunofluorescence or immunohistochemical stains

for κ and λ light chain. If a monoclonal plasma cell process is not established it is necessary to specifically stain amyloid tissue using immunohistochemical techniques.

A monoclonal IgM in the serum often indicates the presence of a malignant lymphoproliferative disorder. The outcome reflects the histology of the underlying lymphoproliferation rather than the type or amount of IgM produced. Waldenström's macroglobulinemia is the syndrome that develops when the IgM levels are high, usually greater than 3 g dl^{-1} . Serum hyperviscosity, anemia, and bleeding can result (Figure 2).

Miscellaneous monoclonal gammopathies (Table 3) include lichen myxedematosus, primarily affecting the skin; light chain deposition disease; types I and II cryoglobulinemia; adult acquired Fanconi syndrome, primarily affecting the kidney; systemic capillary leak syndrome, causing episodic hypotension and hemoconcentration; osteosclerotic myeloma causing blastic bone lesions, associated with neuropathy and endocrinopathy; acquired C1 esterase inhibitor

deficiency, causing episodic hives and angioedema and loss of C3 and C4; and cold agglutinin syndrome, causing hemolytic anemia. Heavy chain diseases are covered in another article in this work.

HYPER-IgM SYNDROME

Ramsay L Fuleihan, Section of Immunology, Department of Pediatrics, Yale University School of Medicine, New Haven, Connecticut, USA

The hyper-IgM syndrome is a rare immune deficiency disorder which was first described in 1961 in two independent reports by Rosen and colleagues and by Burtin. It is characterized by a defect in immunoglobulin isotype switching resulting in low or undetectable serum levels of IgG, IgA and IgE but normal or elevated IgM levels. Most patients exhibit an X-linked mode of inheritance; some families with affected females suggest autosomal recessive or dominant modes of inheritance. The hyper-IgM phenotype has also been associated with ataxia telangiectasia and can present as an acquired disorder that is associated with congenital rubella, administration of anti-epileptic drugs, chronic lung disease, autoimmune hemolytic anemia or tumors. In 1993, five different groups discovered that the X-linked hyper-IgM syndrome results from defects in the gene encoding CD40 ligand (CD40L), a glycoprotein expressed on activated T cells that drives immunoglobulin iso-

type switching in B cells through interaction with CD40.

Diagnosis and clinical characteristics

Most patients with X-linked hyper-IgM present in the first 2 years of life with recurrent sinopulmonary infections, while some patients have presented with *Pneumocystis carinii* pneumonia. Low or undetectable serum IgG, IgA and IgE levels with a normal or elevated IgM level in a boy suggests the diagnosis of X-linked hyper-IgM. The presence of a normal number of mature B cells in X-linked hyper-IgM differentiates it from X-linked agammaglobulinemia. Normal numbers of T cells and T cell subsets with normal T cell proliferation to mitogens differentiates X-linked hyper-IgM presenting with *P. carinii* infection from severe combined immunodeficiency or HIV infection. Identification of a defect in the CD40L

gene confirms the diagnosis of X-linked hyper-IgM. Patients with X-linked hyper-IgM have been found to produce specific antibodies in response to vaccination, but the antibodies are restricted to the IgM isotype. Patients lack germinal centers in their lymph nodes and do not exhibit memory responses to repeated immunizations. Because the genetic defect is not lethal to T cells, carriers have random inactivation of the X chromosome in their T cells. As few as 30% of the carriers' CD4⁺ T cells may express normal CD40L with no apparent effect on immune function (Figure 1).

Patients with X-linked hyper-IgM are also susceptible to infections with *Histoplasma capsulatum* and cryptosporidium; the latter is associated with chronic diarrhea. Other manifestations of the disease include recurrent episodes of stomatitis that may be associated with neutropenia. The cause of the neutropenia is not known; it may be secondary to the development of antineutrophil antibodies (although such antibodies are usually not detected) or to a defect in myeloid differentiation. The presence of autoantibodies has been reported in X-linked hyper-IgM and may lead to the development of anemia, thrombocytopenia or nephritis. Arthritis may result from autoantibodies or be secondary to viral or mycoplasma infections. Patients have an increased risk of developing B cell lymphoproliferative disease that is usually polyclonal but nevertheless can be fatal.

Molecular pathology

Most patients with X-linked hyper-IgM have a defect in the gene encoding CD40L. The gene for CD40L consists of five exons and is located on the X chromosome at Xq26.3–Xq27.1. CD40L is a 39 kDa glycoprotein member of the tumor necrosis factor α family and is expressed transiently on the surface of CD4⁺ T cells. The various reported defective forms of CD40L share an inability to bind to CD40 and consist of single amino acid substitutions, truncations, or in-frame or out-of-frame deletions. To date there has been no correlation between specific mutations and clinical phenotype.

Figure 1 CD4⁺ T cells from a patient with X-linked hyper-IgM, his mother and a normal control were stained 6 h after stimulation with phorbol ester and ionophore. None of the patient's CD4⁺ T cells expressed any detectable CD40L in contrast to >90% of the control's CD4⁺ T cells. Fifty per cent of the mother's CD4⁺ T cells expressed CD40L consistent with her carrier status. ○, IgG1 control antibody; ■, CD40L antibody.

Figure 2 Mechanism of immunoglobulin isotype switching using IgE as an example. When the T cell receptor/CD3/CD4 complex is engaged by MHC and peptide antigen/allergen, interleukin 4 (IL-4) is secreted and CD40L expressed on the cell surface. IL-4 stimulates B cells to initiate ϵ germline transcription. Engagement of CD40 by CD40L enhances ϵ germline transcription and induces deletional switch recombination allowing synthesis of ϵ heavy chain and subsequent IgE production.

A few patients with a phenotype similar to the X-linked hyper-IgM syndrome and apparent X-linked inheritance have been found to have normal CD40L with an unidentified defect in signal transduction through CD40. These patients demonstrate that the cause of hyper-IgM is the absence of a stimulatory signal resulting from the interaction between CD40 and its ligand. Defects in CD40 or its signaling pathway may be responsible for autosomally inherited cases of primary hyper-IgM. In mice, gene targeting of either CD40 or its ligand results in a phenotype that resembles the human disease. Gene-targeted mice lack T cell-dependent immunoglobulin isotype switching, B cell memory responses and germinal center formation.

Pathogenesis of the clinical picture

Failure of interaction between CD40 and its ligand results in a defect in B cell differentiation which is reflected in the patients' serum immunoglobulin levels and their response to immunization. In X-

Figure 3 Consequences of interaction between CD40 and its ligand. (A) Effects of engagement of CD40 by mAb or by CD40L. (B) Functional consequences of inhibition of CD40/CD40L interaction by CD40L mAb, by soluble CD40, or by gene targeting.

linked hyper-IgM, mature B cells do not undergo immunoglobulin isotype switching (Figure 2) nor do they exhibit memory responses. Elevation of IgM levels in some patients but not in others remains unexplained but may be secondary to recurrent infections or to lymphoproliferative disease. Susceptibility to opportunistic infections in X-linked hyper-IgM, in contrast to X-linked agammaglobulinemia, suggests that CD40L plays a direct role in clearing opportunistic infections. Indeed, protection of severe combined immunodeficient mice from *Pneumocystis carinii* infection by reconstitution with human T cells was abrogated by antibody to CD40L. The mechanisms by which CD40L deficiency leads to the development of neutropenia, stomatitis and lymphoproliferative disease have not been determined. In B cells, engagement of CD40 results in the expression of Fas (CD95) and in a susceptibility to Fas-mediated apoptosis. This may be an important mechanism for killing proliferating B cells as well as autoreactive B cells and may explain the development of lymphoproliferative disease and autoimmune disease, two hallmarks of Fas deficiency, in patients with hyper-IgM syndrome. Successful interaction between CD40 and its ligand has further profound effects on normal immune function that are inhibited when the interaction is disrupted (Figure 3).

Therapy

Therapy of X-linked hyper-IgM is currently limited to provision of passive immunity by administration of intravenous immunoglobulin, which reduces the frequency and severity of infections but does not prevent lymphoproliferative disease. Infections are treated aggressively with specific antimicrobial therapy. There are conflicting reports on the benefit of granulocyte-macrophage colony-stimulating factor (GM-CSF) in the therapy of neutropenia. Bone marrow transplantation can cure this disease and may be feasible when an HLA-matched sibling is available. Identification of the genetic defect has allowed carrier detection and prenatal diagnosis and may open the door to gene therapy in the future.

HYPERSENSITIVITY REACTIONS

Rita Mirakian, Department of Immunology, St Bartholomew's and the Royal London School of Medicine and Dentistry, London, UK

Hypersensitivity reactions occur as a result of an immune response that is inappropriate or excessive and causes various types of tissue injuries.

Following Coombs' and Gell's classification in 1963, there are at least four categories of hypersensitivity reaction. The first three, type I (immunoglobulin E (IgE)-mediated), type II (cytotoxic or antibody-dependent cytotoxicity) and type III (immune-complex mediated), are all immunoglobulin-dependent reactions involving a humoral, B lymphocyte-mediated response which operates mainly as a protection against extracellular infections. Conversely, type IV (delayed-type hypersensitivity) is a cell-mediated immune response that is T rather than B lymphocyte dependent. This type of reaction is more effective against intracellular infections (Table 1).

More recently, a type V hypersensitivity reaction has been added, named stimulatory or antireceptor hypersensitivity. This is caused by circulating auto-antibodies stimulating cell receptors of the affected tissues.

The *in vivo* pathologic picture is generally the consequence of overlapping immunologic mechanisms rather than the outcome of a single immune response. Thus, the interaction of cell-mediated and antibody-dependent immune mechanisms determine the type and effectiveness of the immune response.

T_H1 and T_H2 subsets: differential roles

This traditional classification has, however, to be seen in the context of the now recognized paradigm establishing the existence of two fundamentally

Table 1 Classification of immunologic diseases

Type of hypersensitivity	Pathologic immune mechanisms	Mechanisms of tissue injury and disease
Type I Immediate	IgE antibody	● Mast cells and their mediators (vasoactive amines, lipid mediators, cytokines)
Type II Antibody-mediated	IgM, IgG antibodies against tissue or cell surface antigen	● Complement activation ● Recruitment and activation of leukocytes (neutrophils, macrophages) ● Abnormalities in receptor functions
Type III Immune complex-mediated	Immune complexes of circulating antigens and IgM or IgG antibodies	● Complement activation ● Recruitment and activation of leukocytes
Type IV T cell-mediated	CD4 ⁺ T cells (delayed-type hypersensitivity)	● Activated macrophages, cytokines

Reproduced with permission from Abbas *et al* (1995).

polarized forms of specific immune responses which depend on the profile of cytokine production. Recent experimental evidence has shown that CD4⁺ T helper clones produce two distinct (T_H1 and T_H2), mutually exclusive patterns of cytokine secretion whose role is critical for the differential selection of the type of effector mechanism to be activated during an immune response. T_H1 clones mainly produce interleukin 2 (IL-2), interferon γ (IFN γ) and tumor necrosis factor β (TNF β) and are responsible for IgG2a production (in mice) and for cell-mediated immune responses, whereas T_H2 clones mainly secrete IL-4, IL-5 and IL-10 and direct IgG1 and IgE humoral immune responses. T_H0 clones have also been identified as a common precursor subset producing both T_H1 and T_H2 cytokines. Some cytokines, such as IL-3, granulocyte-macrophage colony-stimulating factor (GM-CSF) and TNF α are secreted by the two T cell subsets. T_H1 cells dominate protective responses against intracellular microbial infections and are involved in delayed-type hypersensitivity (DTH). Conversely, T_H2 cells are more efficient towards extracellular host defenses through antibody production, particularly of the IgE isotype. This distinct T_H1 and T_H2 cytokine profile does not exist among naive T cells. The transition toward effect of T_H1 and T_H2 functions occur through an obligate, intermediate state expressing multiple cytokines, but the decision as to what effector function is required is predetermined by a series of factors. Similarly to CD4⁺ T cells, CD8⁺ cells appear to secrete a polarized pattern of cytokines, although they tend to make T_H1 rather than T_H2 cytokines.

Type I hypersensitivity

The first description of an allergic response was made by Prausnitz and Kustner, who succeeded in provoking an allergic reaction by transferring the serum of Kustner, who was reacting to fish, to Praus-

nitz, who was allergic to pollen. Reinjection of fish antigen immediately triggered a wheal and a flare at the site of reinjection. This observation goes back to 1921. It is surprising that the term allergy or atopy (altered reactivity) has become synonymous with a type I hypersensitivity only in more recent times when the term 'allergen' was introduced for proteins and chemicals responsible for this reaction, and the term 'anaphylaxis' was established for the resulting generalized immune reaction. The localized form of anaphylaxis is exemplified by hay fever, asthma, eczema and urticaria (skin wheals). The systemic anaphylaxis characterized by sudden shock and dyspnea, frequently leading to death, occurs in extremely sensitive individuals.

Since the early transfer experiment, one of the main achievements in this field was the discovery by Ishizaka of a novel class of immunoglobulin, the IgE responsible for the type I response. IgE exists in levels between 10 000 and 100 000 fold less than IgA and IgG, respectively.

Characteristics of IgE

1. Like the other immunoglobulins, IgE possesses two light and two heavy chains but, as in IgM, displays five instead of four domains in the heavy chains.
2. It is unable to fix complement or to cross the placenta.
3. It differs from the other immunoglobulin classes in its:
 - (a) activity, which is destroyed by heat inactivation at 56°C for 30 min;
 - (b) shorter half-life (2 versus 21 days for most IgG subclasses), although the sensitized mast cells retain the ability to respond for up to 3 months;
 - (c) ability to bind selectively to specific receptors on mast cells and basophils through its Fc portion specific for ϵ heavy chains.

The IgE receptors enable the IgE to initiate both the afferent and the efferent immune reactivity in the presence of low antigen concentration. Three types of receptors have been identified: FcεRI, FcεRII and εBP.

High-affinity receptor for IgE (FcεRI)

This is the classical IgE receptor present on mast cells and basophils. Recently it has been found also on Langerhans cells of the skin. Its structure consists of one α, one β and two γ chains with the γ chains linked by a disulfide bond. Only the α unit mediates IgE binding, whereas β and γ chains may be involved in signal transduction and all three chains are important for FcεRI function.

Low-affinity receptor for IgE (FcεRII)

This receptor (also named CD23) belongs to the lectin superfamily, although it binds to noncarbohydrate structures on the IgE. In humans, its expression is tightly regulated, being induced by IL-4 and suppressed by IFNγ. FcεRII is generally overexpressed in highly atopic patients and in those affected by parasitic infestations. Its structure consists of a 45 kDa sialoglycoprotein which exists in an α form and a β form. The two isoforms have differing tissue distribution. The β form is expressed on macrophages, B cells, monocytes, platelets and eosinophils only after stimulation, whereas the α isoform is expressed constitutively on B cells. FcεRII on a variety of cells plays a role both in antigen 'capture' and presentation and in effector cell functions.

IgE binding protein (εBP)

εBP, a member of the thiol-dependent lectin superfamily, is attached to the cell membrane by binding to glycolipids and glycoproteins. This receptor is present in various hematopoietic cell types, such as eosinophils and neutrophils, and can be disrupted easily. εBP binds the ε chain through carbohydrate structures. Its role is not fully elucidated.

IgE regulation and function

Atopic individuals produce high levels of IgE in response to particular antigens. This depends on: 1) the nature and dose of the antigen; 2) genetic factors; and 3) the type of cytokine production.

1. Antigens able to evoke a strong immediate type I response are called allergens. These are relatively small and highly soluble proteins which, by entering across mucosal surfaces in very low doses, favor the activation of T_H2 cells and IgE production. Additional factors, i.e. specific

mechanisms of antigen processing, the presence of proteases and for some airborne protein material, the combination with environmental adjuvants (i.e. pollutants, such as smoke, diesel exhaust) might all contribute to the enhancement of IgE synthesis and the clinical manifestation of allergy.

2. If both parents are allergic there is more than a 50% chance that the children will develop allergies; with only one parent being allergic, there will be approximately a 30% chance. A gene associated with atopy has been linked to chromosome 5q31.1, a region where both the gene for IL-4 and IL-13 have also been mapped. This would suggest that polymorphism in the coding region of a differential transcriptional regulation of IL-4 and IL-13 gene expression in atopic individuals could contribute towards T_H2 cell development.
3. T_H2 development and B cell isotype switching to IgE result from an environment rich in IL-4. The IL-4 requirement for T_H2 priming has been demonstrated in IL-4 knockout mice which have an impaired T_H2 response and an absent IgE production. Recently, IL-3, IL-5, IL-6 and TNFα have been claimed to contribute to the IgE isotype switching, whereas IL-12, IL-8, IL-10, IFNγ and transforming growth factor β (TGFβ) have inhibitory effects. The IgE production is initiated by allergic presentation by local APC to T_H2 cells. This subset releases sets of soluble cytokines important in the differentiation and activation of eosinophils (IL-3, IL-5, GM-CSF), in the survival of mast cells (IL-3, IL-4, IL-10) and in IgE production (IL-4, IL-13). In addition to cytokine production, T and B cell physical interaction occurring between CD40 ligand (CD40L) expressed on activated T cell subsets and CD40 expressed on B cells is required for the expression of productive mRNA and for the synthesis of IgE.

Type I hypersensitivity: role in the afferent limb of the immune response

There is evidence that IgE can play a critical role in antigen presentation at the mucosal sites. Cells expressing FcεR on their surface, such as Langerhans cells, follicular dendritic cells, activated B cells and macrophages, are able to 'capture' and 'focus' antigen-bound IgE on their surface, thus enhancing antigen presentation to CD4⁺ T cells. FcεRII is involved in this process.

Type I hypersensitivity: principal role in the effert limb of the immune response

Following antigen stimulation, monomeric antigen-specific IgE binds to Fcε receptors on circulating basophils and mast cells present in the lymphoid areas of the skin and respiratory and gastrointestinal tracts. The result of this interaction is mast cell sensitization. At the second exposure to the same antigen, cross-linking by the multivalent antigen of the surface-bound IgE will occur, causing degranulation of these cells (Figure 1).

Mass cell activation and immune modulator release

In addition to antigen-IgE complex cross-linking, mast cells can also be stimulated by complement components (the anaphylatoxins C3a and C5a). The result of stimulation is a cascade of reactions leading to intracellular influx of Ca^{2+} from the endoplasmic reticulum. Ca^{2+} in the cytoplasm triggers an intracellular series of events which induce the release of two types of mediators: preformed mediators, such as histamine (the most abundant and fastest acting), proteoglycans, proteases and heparin, which are released by exocytosis, and newly synthesized lipid mediators derived from arachidonic acid. Particularly important are three types of metabolites, those derived from the cyclo-oxygenase, such as prostaglandin D_2 (PGD_2) and thromboxane A_2 , those derived from the lipoxygenase, such as leukotrienes (CTB_4 , LTC_4 , LTD_4 and LTE_4), and platelet activat-

ing factor (PAF) (Figure 2). Following activation, mast cells can also release cytokines ($\text{TNF}\alpha$, IL-5, IL-6, IL-8). All of these mediators have essentially three important functions which directly affect target organs:

1. Vasodilatory and increased vascular permeability activities.
2. Chemotactic action on polymorphs, lymphocytes and platelets through neutrophil chemotactic and platelet-activating factors.
3. Spasmogenic activity with a direct effect on bronchial smooth muscle and an indirect increase in mucus secretion.

Different mediators are released from different tissue mast cell and blood basophil subsets, thus in turn triggering different clinical manifestations.

Clinical tests for allergy

Skin-prick tests

These are the most common tests in atopy and they are characterized by an itchy wheal and erythema at the introduction of an antigen into the skin in an allergen-sensitized individual. The reaction site is small, allowing a great number of tests to be done at once. The skin prick test consists of a biphasic reaction. The immediate phase lasts about 1 h, and is caused by the release of histamine from degranulatory mast cells. This is often followed by a late reaction, lasting several hours, which is generally

Figure 1 Induction and effector mechanisms in type hypersensitivity. Antigen presentation is performed at the mucosal level. Production of allergen-specific IgE results from the release of $\text{T}_\text{H}2$ cytokines from activated T cells. IgE binds to mast cells through FcεR and sensitizes these cells. Allergen re-exposure cross-links surface-bound IgE and triggers Ca^{2+} release. This leads to the production of mediators causing allergic symptoms. (Reproduced with permission from Roitt *et al* (1996).)

Figure 2 Lipid mediators of inflammation synthesized by mast cells upon stimulation by antigen binding to IgE. (Reproduced with permission from Janeway and Travers (1995).)

larger, harder and moderately painful. This reaction is caused by the release of PGD₂ and leukotrienes by T cells and eosinophils.

RAST (radioallergosorbent test)

RAST evaluates antigen-specific IgE in the serum. This usually correlates with skin-prick tests. There is also a group of allergic patients who are both skin test- and RAST-negative. These individuals make a local antibody response and this is shown by a positive nasal or bronchial provocation test with specific antigen.

Beneficial role of IgE

If the entry of a parasite is not blocked at the level of the gut by a defensive, neutralizing IgA mechanism, the contact of this agent with IgE-sensitized mast cells and basophils will release immune mediators. The response to helminth and nematode

infections is due to the induction of T_H2 cells to secrete IL-3, IL-4 and IL-5, which promote B cell and mucosal mast cell proliferation and eosinophil activation. The result is an increased IgE production and eosinophilia, which are the hallmarks of this type of immune response. Eosinophils have evolved specifically as a defense against parasites that are too large to be phagocytosed; the mast cells have evolved primarily to localize eosinophils near the parasites and to enhance their antiparasitic function. In contrast to allergy, the IgE response to parasites operates against a broad range of parasitic antigens. This response saturates the high-affinity receptors on mast cells, rendering them refractory to further triggering by parasites.

The effector role in host defenses is mainly performed by the eosinophils and IgE-sensitized mast cell interactions with the parasites via IgE FcεRII and eBP. The consequences are: 1) release of granule con-

tents, including the eosinophil major basic protein which lyses the worms; 2) secretion of mucus, which creates a barrier to the attachment and invasion; and 3) increased vascular permeability and chemotaxis, which allows the penetration of complement, IgG and effector cells back into the gut, thereby enhancing the expulsion of the worms. Furthermore, production of proinflammatory cytokines by activated macrophages ultimately increases mucus secretion and facilitates the expulsion of the worms.

Type II hypersensitivity

Type II hypersensitivity results from antibodies of either the IgG or IgM class binding to specific antigens on a cell surface or extracellular matrix, with subsequent activation of the classical complement cascade. This leads either to direct lytic damage of the target cells or facilitates opsonization by attracting polymorphs and macrophages/monocytes bearing C3bR. C3 components can also bind C3bR on mast cells and basophils and trigger the production of molecules which attract and activate other effector cells. In addition, IgG is able to directly cross-link effector cells. In this case, the antibody acts as a bridge between the target cells and the effector cells through the engagement of Fc receptors on effector cells (Figure 3). It is known that only antigen bound IgG (but not free IgG) can bind Fc γ R with high avidity. Fc γ receptors are present on a variety of effector cells: phagocytic (macrophages, neutrophils), non-phagocytic (platelets, eosinophils), and large granular lymphocytes (killer (K) and natural killer (NK) cells). Different IgG subclasses vary in their ability to bind Fc γ R-bearing effector cells, human IgG1 and IgG3 being able to bind more efficiently than IgG2 or IgG4. The destruction of antibody-coated cells by NK cells is referred to as antibody-dependent cellular cytotoxicity (ADCC) and represents a mechanism by which an antibody can direct an antigen-specific attack by an effector cell lacking specificity for the antigen. Thus, target specificity of NK cells is broader than that of cytotoxic T cells, but it does not occur at random.

Type II reactions can involve the activation of a membrane oxidase complex responsible for the secretion of oxygen radicals. Cytotoxicity also follows the activation of phospholipase A₂, which produces arachidonic acid secretion and consequently leukotriene/prostaglandin release. These vasoactive amines contribute to the target cell damage.

Reactions to red cells represent the most clear examples of type II hypersensitivity. The observation made by Landsteiner, at the beginning of the twentieth century, that the serum of some human blood

donors agglutinates the red cells of other normal blood donors, underlies the basis of the present understanding of two life-threatening reactions: hemolytic anemia of the newborn (erythroblastosis fetalis) and blood transfusion reactions. In both cases, the blood group of the 'donor' does not match with that of the 'recipient'.

Erythroblastosis fetalis

In this condition it is the rhesus (Rh) antigen system on the red cell surface which is responsible for the reaction causing fetal-maternal incompatibility. The name has derived from a similar antigen recognized by the serum of rabbits immunized with rhesus monkey red cells. The human Rh(D) antigen is encoded by a dominant gene which is present in approximately 80% of the population. There are therefore Rh⁺ and Rh⁻ individuals. The disease follows the gradual sensitization of a Rh⁻ mother to the blood group Rh⁺ antigen of fetal red cells bearing the paternal Rh⁺ antigen. This happens at the time of first delivery when the mixing of maternal newborn blood occurs. As a consequence, Rh⁻-specific IgG is made in the postpartum period. With subsequent pregnancies, these antibodies cross the placenta into the fetal circulation and react with fetal red cells, destroying them. Therefore the disease mainly occurs with the second or subsequent Rh⁺-incompatible children. The symptoms are hepatosplenomegaly, elevated bilirubin with jaundice, hemorrhage and kidney failure.

Transfusion reactions

Among the 19 different human blood group systems, the group ABO is the most important. Nearly all individuals make IgM antibodies to the antigens of the ABO system that they lack. These antibodies do not cross the placenta; they occur naturally, without prior immunization, possibly through cross-reactions of similar antigens on a variety of environmental agents. If an individual is blood group A, he or she will be tolerant to A and agglutinate B red cells, and vice versa for a blood group B individual. Conversely, a blood group O person will make anti-A and anti-B as natural antibodies and will only tolerate blood transfusions from group O individuals. Thus, if mismatched blood is transfused, it will cause blood agglutination, complement activation and intravascular hemolysis in the recipient. The hemolytic damage is characterized by jaundice, fever, kidney failure and rapid death of the patient.

A less common example of type II hypersensitivity is the autoimmune hemolytic anemia (AHA), in which patients react to their own red blood cells. The diagnosis is generally made by a positive Coombs

Figure 3 Effector mechanisms in antibody-mediated cell injury. (A) Activation of complement and cell lysis. (B) Activation of complement and recruitment/activation of leukocytes leading to cell lysis. (C) Phagocytosis of opsonized cells. (D) Cell lysis by natural killer cells. (Reproduced with permission from Abbas *et al* (1994).)

test in which the autoimmune reaction is detected by an agglutination obtained with the addition of human-specific immunoglobulin which agglutinates the autoantibody-coated cells.

Finally, in certain autoimmune diseases, type II reactions can cause immunopathologic damage as the autoantibodies are directed to cell surface or to cytoplasmic antigens. Goodpastures syndrome, pemphigus and myasthenia gravis are all caused by auto-

antibodies directed to cell surfaces antigens. In Goodpastures syndrome the autoantibodies are directed to the glomerular basement membrane, causing glomerulonephritis, and sometimes also to the alveolar basal membrane, causing lung hemorrhage. In pemphigus the pathogenetic antibodies are directed to desmosome antigens and cause the breakdown of the epidermis. In myasthenia gravis the autoimmune destruction is directed against acetyl-

coline receptors and is responsible for extreme muscular weakness. Conversely, in other organ-specific autoimmune diseases, such as insulin-dependent diabetes mellitus (IDDM) and Hashimoto's thyroiditis, the autoantibodies are mainly directed against cytoplasmic antigens (islet cells and thyroid peroxidase, respectively). Their pathogenic relevance is still uncertain. There are indications that IDDM and Hashimoto's disease might be caused by a T rather than B cell mediated mechanism.

Type III hypersensitivity

Antibodies binding to equivalent amounts of soluble antigens give rise to immune complex formation. The antigens involved in inducing the pathogenic immune response can be either foreign or self, and the antibodies either IgG or IgM. When complexes are formed, they usually activate complement and then bind to C3b receptors on erythrocytes. The erythrocytes are then responsible for removing complexes from the plasma and transporting them to the sinusoids of the liver and spleen, where they are removed by macrophages. However, if immune complexes are formed in great excess of antigen, or if the complex is very small and soluble, the reticuloendothelial system will not be able to degrade them efficiently. These complexes will circulate in the blood and subsequently deposit in various tissues of the body, inducing local inflammation. The resulting pathogenic features depend on the sites of immune complex deposition.

Factors that influence immune complex deposition

1. Size: larger immune complexes fix complement more efficiently and are removed more quickly than those of medium size.
2. Isotype: IgA complexes do not bind efficiently to erythrocytes, thus they tend to deposit to a greater extent.
3. Defective phagocytosis and/or complement binding systems which allow immune complexes to bind to the endothelial wall.
4. Biochemical properties of the antigen and antibody: altered glycosylation of IgG has been found in rheumatoid arthritis and this may hamper phagocytosis.
5. Hemodynamic factors: the plasma goes through the capillary walls of the glomeruli and synovia at high hydrostatic pressure, thus facilitating immune complex deposition at these sites.

Immune complexes mediate the inflammatory reaction through several mechanisms:

1. Activation of complement components, with production of C3a and C5a fragments (anaphylatoxins) which bind to complement receptors on:
 - (a) basophils and mast cells, causing the release of preformed and newly formed mediators, such as histamine, PGD₂, PAF, leukotrienes and cytokines. This results in the series of events already described for mast cell degranulation following cross-linking by antigen of mast cell-bound IgE, i.e. increase in vascular permeability, which facilitates the deposition of immune complexes in the blood vessel wall and further production of complement, recruitment of inflammatory cells and smooth muscle contraction;
 - (b) polymorphonuclear leukocytes, causing increase in their adherence to the vessel walls, in their ability to ingest particles and in their attraction to the affected areas.
2. Binding to Fc receptors on basophils and platelets, triggering, on the one hand, the release of vasoactive amines, which leads to increase in vascular permeability and hemorrhage, and, on the other, platelet aggregation and microthrombosis.
3. Stimulating macrophages to produce pro-inflammatory cytokines.

Diseases caused by immune complexes generally follows:

1. *Persistent bacterial or viral (low-grade) infections: streptococcus, leprosy, syphilis, viral hepatitis.* Acute post-streptococcal glomerulonephritis is due to immune complex deposition on the basement membrane of the glomeruli. In lepromatous leprosy and secondary syphilis, the mycobacterium and the treponema antigens, respectively, can cause deposition of complexes in the joints, skin and kidney, with consequent local damage.
2. *Persistent exposure to and inhalation of environmental antigens, i.e. moulds and animal danders.* Examples are the extrinsic alveolitis found in farmers' lung and pigeon fanciers' lung. The antibody involved is IgG, not IgE.
3. *Persistent autoantibody formation in autoimmune diseases, such as systemic lupus erythematosus (SLE) and rheumatoid arthritis (RA).* SLE is characterized by autoantibodies against nuclear constituents, such as DNA and nucleoprotein antigens. Large numbers of immune complexes are produced, tending to deposit in the small vessel walls of the glomeruli, joints and brain and causing injury. In RA, IgG

Table 2 Delayed hypersensitivity reactions

Type	Reaction time	Clinical appearance	Histology	Antigen
Contact	48–72 h	Eczema	Lymphocytes, later macrophages, edema of epidermis	Epidermal, e.g. nickel, rubber, poison ivy
Tuberculin	48–72 h	Local induration	Lymphocytes, monocytes, macrophages	Intradermal, e.g. tuberculin
Granuloma	21–28 days	Hardening, e.g. skin or lung	Macrophages, epithelioid cells, giant cells, fibrosis	Persistent antigen–antibody complexes or non-immunoglobulin stimuli, e.g. talc

Reproduced with permission from Roitt *et al* (1996).

hypersensitivity, foreign antigen presentation is performed by specialized Langerhans cells (HLA class II⁺, CD1⁺, FcγRII⁺) of the skin. These cells can process the antigen and transport it to the paracortical areas of the draining lymph nodes, where contact with naive T cells occurs and memory CD4⁺ T cells are generated. In addition, epidermal keratinocytes may be able to present antigen directly to class I HLA-restricted T cytotoxic cells. The elicitation step is triggered by the re-exposure of the sensitized skin to the same antigen. Activated endothelial cells lining postcapillary venules operate as antigen-presenting cells and present the foreign antigen to primed CD4⁺ T cells. IFNγ produced by CD4⁺ T cells is responsible for upregulation of a range of adhesion molecules and of HLA molecule expression on dermal endothelial cells and on keratinocytes, which further increases the efficiency of local antigen presentation. Adhesion molecules on endothelial cells bind to the corresponding ligands on leukocytes, thereby attracting them into the inflammatory site. Moreover, the activation of keratinocytes and macrophages by IFNγ produces proinflammatory cytokines, which enhance T cell and other leukocyte recruitment until the source of foreign antigen is eliminated by macrophages. Once macrophages are attracted to the skin, downregulation begins. The skin inflammation peaks within 72 h, when the epidermis becomes edematous. CD8⁺ cytotoxic T cells are also involved in the destruction of the hapten-conjugated epidermal cells. Suppression of the inflammatory reaction is mediated by the release of PGE produced by macrophages and keratinocytes and by TGFβ from mast cells and keratinocytes.

Tuberculin hypersensitivity

Tuberculin hypersensitivity was originally observed by Koch in patients with tuberculosis, and subsequently found in patients sensitized by *Mycobacterium leprae*, *Leishmania*, fungi, protozoa, and also by nonmicrobial agents. The reinjection of the spe-

cific sensitizing agent produces a generalized reaction of fever and vomiting and a local reaction of induration and swelling, reaching a peak at 48 h. The skin reaction is used to test for sensitivity to various organisms following previous exposure. After tuberculin challenge, cytokines, such as TNFα, are produced by antigen-specific T cells and these mediators are able to upregulate adhesion molecule expression on endothelial cells of dermal vessels. Adhesion molecules bind to corresponding receptors on leukocytes, thus recruiting inflammatory cells to the site of the reaction. Consequently, the migration of these inflammatory cells from the vessels into the dermis leads to the disruption of collagen structure. The tuberculin lesion usually resolves within a week but if the lesion progresses then it becomes granulomatous.

Granulomatous hypersensitivity

This reaction occurs as a result of the intracellular persistence of an antigen, usually microbial, particularly if it cannot be destroyed by macrophages. The reaction represents a defensive mechanism which is not always successful. Relevant diseases are leprosy, tuberculosis, schistosomiasis, sarcoidosis, Crohn's disease, berylliosis and Wegener's granulomatosis. Clinically, this is the most important form of delayed hypersensitivity. Antigen is presented to activated T cells which secrete proinflammatory cytokines (IFNγ, TNFβ). Cytokines are responsible for the activation of macrophages, whose role is to limit the dissemination of the intracellular microorganisms. When macrophages fail, chronic inflammation occurs. Following cytokine stimulation macrophages can fuse together and form giant cells which function to isolate the pathogens. Characteristically, granulomas consist of a central area of macrophages surrounded by lymphocytes. In tuberculosis the central zone can become totally isolated and the tissue undergoes necrosis. Macrophages and giant cells surround this area. Lymphocytes and

fibroblasts constitute the outer mantle. Foreign body reactions, such as talc and silica, can also present with granulomatous formation but they are distinct because of the absence of lymphocytes.

Measurement of cell-mediated immunity

Tests are developed to assess T cell memory, not protective immunity.

1. *Delayed hypersensitivity skin tests.* The antigen is injected into the skin and the positive inflammatory lesion is documented at the site of injection 48 h later (Mantoux test).
2. *Lymphocyte transformation tests.* This is a test to assess T cell memory. Sensitized lymphocytes are cultured in medium containing specific suspected antigen. A radioactively labeled DNA precursor (thymidine) is added, the mixture incubated, and the incorporation of radioactivity measured. The blastogenesis falls in subjects who are immunodepressed.
3. *Ability to produce cytokines following re-exposure to specific antigens.* Lymphocytes and macrophages are incubated with antigen; memory T cells will produce T_H1 and T_H2 cytokines, which can be measured in the supernatants of the cultured cells and within the cell lysates.

Type V hypersensitivity

Type V hypersensitivity occurs when autoantibodies are produced against cell surface receptors, with subsequent stimulation of the receptor. The most common clinical example is found in Graves' thyrotoxicosis, which, in up to 80% of cases, is characterized by the presence of circulating autoantibodies to the thyrotropin (TSH) receptor. There is a correlation between the autoantibody titer and the severity of the clinical condition, as the antibody stimulates via the same mechanism of adenylyl cyclase activation used by TSH itself. More recently, other clinical examples of type V reactions are gradually emerging, such as autoantibody against the β_1 -adrenergic receptor in myocarditis.

IDIOPATHIC THROMBOCYTOPENIC PURPURA

Robert McMillan, Scripps Clinic, La Jolla, California, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Idiopathic thrombocytopenic purpura (ITP) manifests into two relatively distinct clinical syndromes: acute ITP and chronic ITP. Both are characterized by immunologic destruction of the blood platelets. Because these syndromes differ significantly, they will be discussed separately.

Acute ITP

Acute ITP is a self-limited disorder occurring almost exclusively in children, most commonly between the ages of 2 and 5; there is no sex predilection. A similar syndrome occurs occasionally in adults. The disorder frequently appears 1–6 weeks after a viral illness and usually presents with the abrupt onset of petechiae, bruising and often epistaxis. More serious bleeding from the gastrointestinal tract occurs less commonly and central nervous system bleeding (the most feared complication) is rare (0.5–1.0%). Physical examination shows bleeding manifestations consistent with the level of the platelet count. Enlargement of the spleen is infrequent.

The initial platelet counts are often very low ($<10\,000\ \mu\text{l}^{-1}$); the leukocyte count and hemoglobin are normal unless significant bleeding has occurred. Bone marrow examination shows normal or increased numbers of megakaryocytes. Elevated levels of platelet-associated immunoglobulin G (IgG) are seen in essentially all patients with acute ITP, although recent studies show that this assay is relatively nonspecific and reflects primarily the presence of young platelets with increased α granule IgG. Antigen-specific autoantibodies are rarely demonstrable and, if present, are borderline positive.

Pathogenesis

Little experimental data are available. The fact that acute ITP is frequently seen after a viral illness suggests that the child may be responding to viral antigens by antibody production, immune complex formation and subsequent platelet destruction. Plate-

let removal may be due either to the absorption of viral antigens on to the platelet surface followed by antibody binding and destruction, or to the binding of preformed immune complexes to the platelet Fc receptor, with subsequent destruction. The clinical observation that these patients frequently respond to intravenous gammaglobulin or to anti-D antibody, both of which block the Fc receptors on phagocytic cells, suggests that platelets are destroyed primarily by phagocytosis. Since patients with acute ITP may respond to splenectomy (although this is rarely employed), the spleen is probably involved in platelet destruction.

Therapy

About 80–90% of patients with acute ITP recover spontaneously within the first 6 months; another 5–10% of patients recover over the next several months. Recovery occurs regardless of the therapy which is administered. Three potential therapeutic approaches have been championed by different investigators: 1) intravenous gammaglobulin; 2) high doses of corticosteroids; and 3) no therapy. In view of the self-limited course of acute ITP, some physicians advise no therapy because the mortality rate is extremely low ($<1\%$). However, the fear of severe mucosal bleeding or central nervous system bleeding pushes most physicians to treat their patients. In general, patients without mucosal bleeding, platelet counts $>20\,000\ \mu\text{l}^{-1}$ and a normal bleeding time can be safely observed; others should be treated. Randomized studies show that treatment of patients with either intravenous gammaglobulin or high-dose corticosteroids results in a more rapid recovery of the platelet count than is seen in untreated patients. Due to the low mortality rate of acute ITP, it is not possible to show a survival advantage of either treatment or no treatment. Platelet transfusions are indicated only under emergency circumstances for control of significant bleeding.

A certain proportion of children with acute ITP

fail to improve spontaneously (5–10%) and this group is felt to have an autoimmune condition similar to chronic ITP, which will be described next.

Chronic ITP

This is an autoimmune disorder which occurs most commonly in adults between the ages of 20 and 50 and is more common in women than in men (approximately 2:1). Unlike acute ITP, this disorder appears more insidiously, and extremely low platelet counts and severe mucosal bleeding are uncommon, although they may occur. Physical findings, as with acute ITP, reflect the degree of thrombocytopenia. An enlarged spleen or the presence of enlarged lymph nodes suggests another cause. A similar disorder, often associated with autoantibodies, is seen with a variety of illnesses, including collagen vascular disorders (e.g. systemic lupus erythematosus), lymphoproliferative disorders and certain infections, particularly human immunodeficiency virus (HIV). Blood counts are normal, except for the reduced platelet count, and bone marrow examination shows normal or increased numbers of megakaryocytes. Somewhat surprisingly platelet production studies show that, in the majority of chronic ITP patients, platelet production is either normal or reduced, rather than increased as would be expected. This suggests that the autoantibody may be binding to similar antigens on megakaryocytes and effecting thrombopoiesis.

Elevated levels of platelet-associated IgG are seen in about 90% of patients, but, as noted above, these findings are nonspecific. However, unlike acute ITP, antigen-specific platelet-associated and plasma autoantibodies can be demonstrated in about 80% and 50% of patients, respectively. Autoantibodies are most commonly directed to either the platelet glycoprotein IIb/IIIa complex (the platelet fibrinogen receptor) or to the glycoprotein Ib/IX complex (the platelet von Willebrand factor receptor), although autoantibodies rarely bind to epitopes which interfere with platelet function. As shown in Table 1, antibodies to the former complex occur more com-

monly. Other glycoproteins and glycolipids have been implicated as autoantigens in ITP.

Pathogenesis

Chronic ITP is due to the formation of an autoantibody against a platelet-associated antigen which results in subsequent phagocytosis of platelets by the reticuloendothelial system. The studies of Harrington and Shulman in the 1950s and 1960s showed that infusion of blood or plasma from ITP patients into normal recipients resulted in thrombocytopenia. This antiplatelet factor could be adsorbed with platelets and was present in the IgG-rich fraction of human plasma. Subsequent studies have shown that the autoantibody is produced *in vitro* by both splenic and bone marrow cells from patients with chronic ITP and that the autoantibody binds to both platelets and megakaryocytes. The importance of the spleen in disease pathogenesis, as both a source of autoantibody production and a platelet destruction site in ITP, is supported by the clinical observation that approximately two-thirds of patients are cured of their disease by removal of this organ. Autoantibody studies done before and after surgery show that levels of both platelet-associated and plasma autoantibodies fall precipitously and approach normal levels in patients responding to splenectomy. Conversely, autoantibody levels remain high in those who do not.

The role of complement activation in chronic ITP is unclear. Platelet-associated C3, C4 and C9 levels are elevated on ITP platelets, and *in vitro* incubation of platelets with selected autoantibodies results in binding of C3, C4 and C9 to the platelets and subsequent platelet lysis. How important complement activation is under *in vivo* circumstances is not known.

Although there have been numerous studies on cellular immunity in chronic ITP, the role of cellular immunity in this disorder is unclear. The present evidence suggests that the humoral immune system is the more important.

Platelet destruction in ITP is due to autoantibody binding to antigen, with or without complement activation, followed by phagocytosis of platelets by the reticuloendothelial system. Although complement-mediated platelet lysis, initiated by selected antiplatelet antibodies, has been demonstrated *in vitro*, phagocytosis is thought more important *in vivo*. Phagocytosis can be triggered by either the Fc portion of the IgG molecule or by platelet-bound C3b. The Fc mechanism is known to be important because therapy with either intravenous gammaglobulin or anti-D antibody results in an increase in the patient's platelet count in many chronic ITP patients and the mechanism of action of both agents is thought due

Table 1 Autoantibody results in patients with chronic ITP^a

Patients	Platelet-associated antibody	Plasma antibody
Total studied	142	128
Total positive	112	54
Anti-GPIIb/IIIa	81	43
Anti-GPIb/IX	24	7
Both autoantibodies	7	4

^aAutoantibody was measured using the immunobead assay (McMillan, 1990).

to Fc blockade. In addition, a few patients have been treated with an anti-Fc monoclonal antibody, with temporary improvement of their platelet count.

Therapy

Patients with chronic ITP are treated initially with high doses of corticosteroids ($1\text{--}2\text{ mg kg}^{-1}\text{ day}^{-1}$). Approximately 75–80% of patients will respond by increasing their platelet counts; however, upon tapering this treatment the majority relapse. It is estimated that about 10% of ITP patients are cured with corticosteroids. However, the mainstay of therapy in chronic ITP is splenectomy, which results in a complete and lasting normalization of the platelet count in approximately 60% of patients; an additional 10–15% show persistent improvement of their platelet counts to safe levels ($>30\,000\ \mu\text{l}^{-1}$).

Treatment of the 25–30% of patients who do not respond to corticosteroids and splenectomy is much more difficult. Multiple therapies have been tried with varying degrees of success, including: danazol, colchicine, cyclophosphamide, azathioprine, IgG and immune complex adsorption from plasma by insolubilized staphylococcal protein A, high-dose intravenous cyclophosphamide, and combination chemotherapy. Patients who are refractory to corticosteroids and splenectomy have significant morbidity and mortality from both the therapy and their disease. The overall mortality rate in chronic ITP is approximately 4%; however, refractory patients have a mortality rate closer to 15–20%.

IDIOTYPE

Constantin A Bona, Department of Microbiology, Mount Sinai Medical School, New York, USA

About 50 years ago, it was demonstrated that antibody molecules bear antigenic determinants similar to foreign antigens and they can be defined by immunoglobulin (Ig)-specific sera prepared in xenogeneic or allogeneic animals. These studies led to the definition of two types of antigenic determinants called isotypic and allotypic specificities.

In 1955, Slater and coworkers studied the specificity of antisera prepared in rabbits against human myeloma proteins. They observed that such antisera still reacted with the initial immunogen after extensive absorptions on unrelated myeloma proteins or

normal immunoglobulins. This new category of antigenic determinants was called 'individual' antigenic specificities. Several years later, Oudin and Kunkel described several antigen specificities on rabbit and human antibodies. Oudin coined the term 'idiotype' from the Greek – which means 'identical form' – for this new antigen borne by immunoglobulins.

Further immunochemical studies localized the idiotypic determinants initially on Fab fragments and later on Fv fragments. These studies led to the conclusion that the idiotypes are markers of variable genes encoding the specificity of antibodies or of the

immunoglobulin receptor of clones exhibiting the same antigen-recognizing specificities. Studies conducted in the early 1980s showed that idiotypic determinants can also be serologically defined on the antigen receptor of T cells.

It is now generally accepted that the idiotype represents the antigenic determinants of variable regions or phenotypic markers of variable region genes encoding the specificity of a lymphocyte antigen receptor. Each individual antigenic determinant which makes up the *idiotype* of a given receptor is termed an *idiotope*.

Immunochemical requirements for the expression of idiotypes

Initial studies carried out with human myeloma proteins and rabbit antibodies have shown that both variable regions of heavy and light chains contribute to idiotypic determinants. These results strongly indicated that the idiotypes are conformational antigenic determinants. The development of new techniques, such as western blotting assay, preparation of hybrid heavy-light chain molecules by immunochemical methods or transfectoma technology, and the utilization of synthetic peptides corresponding to protein sequences of variable regions, showed that there are situations in which a given idiotype is localized on only heavy or light chain or in very rare cases on both. The idiotype located on a single chain or identified by anti-peptide antibodies are more likely sequence dependent and therefore are linear antigenic determinants.

Combined utilization of serologic properties of anti-idiotype antibodies with electron microscopic analysis allowed the mapping of idiotopes on V-regions of streptococcus group A-specific antibodies. These studies showed that the idiotopes could individually be located over much of the surface of the V region extending from the combining site to the constant region.

Classification of idiotypes

Idiotypes are generally defined by serologic reagents collectively designated as anti-idiotype antibodies. Several criteria were used to classify the idiotypes based on the type of interaction between idiotypes and anti-idiotype antibodies.

The immunochemical criterion used to classify the idiotype consists of the effect of antigen on the interaction between idiotype and anti-idiotype antibodies. In the case of some idiotypes, this reaction is inhibited by the antigen, whereas in other cases it is not. Because it is generally accepted that hyper-

variable regions make up the combining site of antibodies and amino acid residues are responsible for binding to antigens, antigen-inhibitable idiotypes are considered 'idiotypes associated with the combining site'.

The second category of idiotypes that interact with anti-idiotype antibodies are non-antigen inhibitable and are considered to be located outside the combining site, and are usually called 'framework associated idiotypes'.

Genetic criteria were used to classify the idiotypes at a clonal level. Individual idiotypes result from a unique somatic recombination event of immunoglobulin genes or as a consequence of somatic mutation. Individual idiotypes are expressed on the antigenic receptor of a single lymphocytic clone in a single individual of a given species and are not inherited.

Cross-reactive idiotypes (CRI), (IdX) are expressed on antibodies or T cell receptors (TCRs) with the same specificity from various individuals. This category of idiotypes is inherited in a mendelian manner and probably represents phenotypic markers of germline genes. Cross-reactive idiotypes were identified on antibodies with the same antigen specificities produced in various species: amphibians, mice, rats, guinea pigs, pigs, rabbits, monkey and humans. They have been identified on antibodies against foreign antigens (haptens, polysaccharides or proteins), cellular antigens (HLA-DR, H-2, erythrocyte antigens such as Rh, I or P), self antigens (DNA, Sm, thyroglobulin, basal membrane, collagen II), and cellular receptors (such as AChR, TSHR, insulin receptor, and β receptor).

In 1981, we classified the cross-reactive idiotypes into three major groups:

1. *IdX linked to allotype*. These idiotypes are expressed in all inbred or recombinant inbred strains which share the same allotypes of heavy or light chains. The restriction of the expression of the V region genes of immunoglobulin molecules by C genes is not fully understood.
2. *Interstrain idiotypes*. This category of idiotypes is expressed on various inbred strains or on a major fraction of individuals of an outbred species independent of genetic allelism of the constant region.
3. *Interspecies idiotypes*. These are cross-reactive idiotypes shared by antibodies displaying the same antigen specificity produced by individuals of various species. These IdX are markers of germline genes that are conserved during evolution.

The same idiotypic determinants of antibodies with the same antigen specificity can be shared

independently on various immunoglobulin classes or isotypes. This phenomenon is due to the ability of a given V_H region gene to recombine with various constant region genes during clonal development, differentiation and switching of B cells subsequent to antigen stimulation.

The idiotypes were also classified based on their expression in the immunoglobulin repertoire, variation during the immune response, or their role in the immune response. With respect to their expression, the idiotypes can be classified into:

1. Dominant idiotypes expressed on the majority of antibodies exhibiting the same antigen specificity. As an example, one may cite T15 IdX expressed on antiphosphocholine antibodies, A5A IdX expression on ACHO-streptococcus A polysaccharide-specific or CRI of arsonate-specific antibodies. The dominance of certain idiotypes can be related to the phylogenetic selection of clones involved in the immune response against microbes.
2. Minor idiotypes expressed on a small fraction of antibodies produced in a response against a particular antigen.
3. Silent idiotypes, which are not expressed during a conventional immune response but which can be detected or even can become dominant subsequent to activation of clones by anti-idiotypic antibodies or certain regimens of immunization.

From a functional point of view, the idiotypes can be classified into two major categories:

1. Conventional idiotypes, which can be defined by anti-idiotypic antibodies obtained in various animals and which do not show variations during the immune response.
2. Regulatory idiotypes were described on antibodies specific for both foreign and self antigens. They are involved in the regulation of responses to antigen and may show variations during the immune response.

Polymorphism of the idiotypic system

The localization of idiotype on Fv fragments of antibodies and the subsequent concept that the idiotypes are phenotypic markers of variable region genes encoding the antigen receptor of lymphocytic clones, led to another concept; namely, that there is a relationship between the combining site, hypervariable regions and idiotypes. However, this concept was challenged by the experiments of Oudin and Cazenave, who showed for the first time that the same idiotype can be shared by antibodies with various specificities. This observation clearly indicated

that the idiotypic system is polymorphic. The polymorphism of the idiotypic system has important implications for the physiology of the immune system, indicating the existence of a certain degree of connectivity between lymphocyte clones and a possible cross-regulation by anti-idiotypic antibodies produced by B cells or by anti-idiotypic T cells. There are numerous experimental data demonstrating that the idiotypic determinants expressed on the lymphocytic receptor are the target of regulatory processes involved in clonal expansion or suppression.

The idea of polymorphism of the idiotypic system is supported by several observations demonstrating that the cross-reactive idiotypes can be shared by antibodies with various specificities, antibodies specific for various epitopes of multivalent antigens, or antibodies with unknown specificities.

The idiotypes shared by antibodies specific for various antigens were initially described by Oudin and Cazenave, who found that rabbit antibodies specific for chicken, duck, and turkey ovalbumin share a serologically defined cross-reactive idiotype. This discovery was quite surprising, as the idiotypes were considered clonal markers. This observation was confirmed in various systems. Thus, cross-reactive idiotypes were found on antibodies specific for the immunodominant sugar of lipopolysaccharide of gram-negative bacteria, on antibodies specific for various type A influenza virus subtypes, etc.

It should be mentioned that idiotype-like structures can be shared by antibodies and other substances which are not immunoglobulins. Volkanis and Kearney actually showed that C-reactive protein which binds to phosphocholine and phosphocholine-specific antibody both interact with T15 anti-idiotypic antibodies. T15 idiotype is a dominant idiotype shared by murine phosphocholine-specific antibodies.

Idiotypes shared by antibodies specific for various epitopes of an antigen molecule were also demonstrated in several systems. Such shared idiotypes have been identified on guinea pig antibodies specific for different epitopes of hen egg white lysozyme, allo-type-specific antibodies or antibodies specific for PR8 virus laboratory-selected variants that differ from the parental virus by a single point mutation.

Shared idiotypes were also identified on antibodies with unknown specificities. These types of antibody are called 'parallel sets'. It is unknown whether these antibodies represent genuine anti-anti-Id antibodies interacting with the idiotypes of anti-Id antibodies or they exhibit an unidentified antigen specificity. In practice, it is very difficult to exhaust by screening all possible antigen specificities.

The antibodies sharing cross-reactive idiotypes can

be encoded by V genes from various V_H or V_K families. This indicates that contacting residues able to interact with the same anti-idiotypic antibody which serologically defines a given idiotypic can be produced by various combinations of V_H or V_K families.

Recognition of idiotypes by T cells

It is well documented that T cells can recognize the antigenic determinants of immunoglobulins as they are able to recognize foreign, allo or syngeneic antigenic determinants. This was shown for various subsets of T cells, such as suppressor or helper regulatory T cells or effector cells mediating cytotoxic, delayed-type hypersensitivity or contact sensitivity reactions. Anti-idiotypic T cells can recognize serologically defined idiotypes as well as idiotypes that are not recognized by anti-idiotypic antibodies. A regulatory idiotypic shared by PC-binding antibodies recognized by T cells but not by anti-idiotypic antibodies was identified by Gleason and Kohler. Recent data suggest that the recognition of idiotypes in association with major histocompatibility complex (MHC) antigens requires the processing of native immunoglobulins by antigen-presenting cells in the case of both CD4 and CD8 T cells.

Idiotypes of TCR

TCR, like Ig of B cells, bears idiotypic antigenic determinants that can be located on α or β chain or both. These determinants should be distinguished from antigenic determinants borne by $V\alpha$ or $V\beta$ chains encoded solely by $V\alpha$ or $V\beta$ gene segments. These latter can be considered as the equivalent of V_H or V_K subgroup or allotypic determinants.

Idiotypic determinants of TCR were defined by anti-idiotypic antibodies or T cells. In early studies, Eichmann and Rajewsky showed that the T cells and B cells exhibiting the same antigen specificity, i.e. ACHO carbohydrate of streptococcus A, share the same idiotypic. These studies were not confirmed later. Actually, idiotypic determinants of TCR are generally different from those of Ig because of the low degree of homology between CDRs of V genes of immunoglobulins and of TCR. Idiotypic determinants defined by antibodies or by T cells were identified on various subsets of T cells such as suppressor and helper T cells, and T cells mediating delayed-type sensitivity, contact sensitivity, or resistance against graft-versus-host reaction. It is important to mention that antibodies specific for idiotypes of TCR can function as antigen surrogates; namely, to activate or suppress T cell function.

Structural correlates of idiotypes

Two major approaches were used to determine the structural correlates of idiotypes. The first method consisted of mutational analysis of antibody molecules followed by screening with anti-Id antibodies, and the second method employed X-ray crystallographic analysis of the Fab fragments of Id-anti-Id complexes.

Comparison of the sequences of the V_H regions of anti- α 1-3 dextran monoclonal antibodies reacting with anti-Id specific for J558 or MOPC106 myeloma proteins established that one amino acid difference located in the CDR3 of V_H expressed in an anti- α 1-3 dextran monoclonal antibody (i.e. MOPC104) accounted for the expression of an individual idiotypic specificity.

Similar studies of the sequences of V genes encoding antibodies specific for haptens such as 4-hydroxy-3-nitrophenyl-acetyl (NP), *p*-azo phenyl arsonate (Ars) or phosphocholine (PC) demonstrated that one to a few amino acids correlate with idiotypes. These observations strengthened the concept that individual idiotypes are the result of somatic mutations which took place in an individual clone.

Site-directed mutagenesis contributed efficiently to the definition of the amino acid residues of idiotypes involved in the interaction with anti-idiotypic antibodies. The information provided from these studies established that:

1. Single amino acid substitutions may have dramatic effects on the expression of individual or regulatory idiotypes.
2. Amino acid residues in both CDRs and frameworks may contribute to the expression of idiotypes but that CDR3 appears to have a prominent importance.
3. Both V_H and V_L chains can contribute to the expression of a given idiotypic.

These conclusions are strongly supported by X-ray crystallographic analysis of Id-anti-Id complexes which represent the definitive and most subtle approach to determining the nature of idiotypic-anti-idiotypic interactions.

Study of Fab complexes of an anti-lysozyme and anti-Id monoclonal antibody showed that 13 amino acid residues of the idiotypic interact with the anti-idiotypic antibody. These 13 contact residues are associated with five CDRs and one framework. In this case the idiotypic is a conformational epitope representing a solvent accessible area of approximately 800 Å determined by the participation of various CDR loops of both the V_H and V_L region.

IDIOTYPE, INTERNAL IMAGE

Constantin A Bona, Department of Microbiology, Mount Sinai Medical School, New York, USA

The idiotype network theory proposed by Jerne suggests that, in the steady state, the immune system is in equilibrium due to the existence of complementary clones that are interconnected by idiotypic links. This concept implies that the receptor of a lymphocytic clone is able to recognize a particular antigen by its paratope, and to be recognized by other clones through idiotypes which are expressed on the antigen receptor of all lymphocytic clones. Each receptor has several idiotypes which are collectively designated as its idiotype. Operationally, the clones of the immune system can be divided into two major categories: those which recognize the antigen (Ab1) and those which recognize the idiotypes (Ab2). This classification is strictly operational, since one of the essential features of the network theory is that it introduces the concept of internal image of the antigen as a statistical necessity. This means that among the multitude of three-dimensional, steric structures of the variable domains of lymphocytic receptors, there are structures which are similar, if not identical, to the epitopes of conventional foreign or self antigens.

Lindeman suggested that it is likely that such structures are expressed on anti-idiotype (anti-Id) antibodies, because if the idiotype of an Ab1 associated with the combining site is the negative imprint of the antigen, the idiotype of an Ab2 could be the

positive imprint of the antigen, i.e. its internal image. The obvious conclusion to this concept is that the internal antigens play a role equally as important in the network as external antigens because they represent links between the outside world of the antigens and the immune system of a given individual.

Two major functions can be thought of for the internal antigens. First, the idiotypes as internal antigens can prime the Ab1 precursors for self or foreign antigens. From a physiological standpoint, this is important because the host can respond promptly to an invader. There are data to indicate that a mother's idiotypes transferred via the placenta can actually expand clones which become dominant during a conventional immune response elicited by a bacterial polysaccharide and which are otherwise silent.

The second function of internal image can be related to the stimulation of memory cells and particularly their long survival after extinction of the immune response related to clearance of the antigen. Minute amounts of residual internal image antibodies could have a stimulatory effect on memory cells, as it is well established that the lymphocytic receptor of such cells have high affinity for antigen and therefore a surrogate stimulus may suffice to stimulate their proliferation and survival. The first demonstration of an internal image idiotype came

from the work of Sege and Peterson. These investigators showed that anti-idiotypic antibodies prepared against bovine anti-insulin antibodies were able to mimic some of the properties of insulin. Such antibodies bound receptor and stimulated some physiological properties of insulin itself.

Anti-idiotypic antibodies carrying the internal image

The idiotypes of a lymphocytic receptor can be located on various segments of the variable regions and may require the contribution of both the heavy and light chain. Some idiotopes are associated with the combining site, since their interaction with anti-idiotypic antibodies can be inhibited by antigen. Other idiotypes are located on variable region segments which are not involved in the combining site; the interaction of these idiotypes, collectively designated the 'framework associated idiotypes', with anti-Id antibodies is not antigen inhibitable. Therefore, it appears that the clones recognizing idiotypes (Ab2) represent a heterogeneous population displaying various specificities.

These clones express surface immunoglobulin and secrete antibody which can be classified into four major categories (Figure 1):

1. Ab2 α , which is specific for idiotypes associated with the framework segments of the variable region. The binding of Ab2 α to Ab1 does not alter the binding of Ab1 to antigen. These antibodies can exhibit a regulatory effect, priming

or suppressing Ab1 clones, but they cannot replace an antigenic stimulus. It was shown that allogeneic A/J anti-T15Id antibodies, which are not antigen inhibitable, can induce a long-lasting suppression of T15⁺ anti-phosphocholine antibodies. Similarly, a monoclonal antibody specific for a cross-reactive idiotypic shared by antibodies specific for influenza virus neuraminidase was able to prime animals for a specific response but not elicit by itself anti-neuraminidase antibodies.

2. Ab2 γ are antibodies that recognize combining site-associated idiotypes. Such antibodies can inhibit the binding of Ab1 to antigen but cannot elicit an Ab1 response when injected into an animal. Such antibodies can have a regulatory effect, despite the fact that they are devoid of internal antigen properties.
3. Ab2 β are anti-idiotypic antibodies mimicking the antigen. Such anti-Id antibodies bind to the combining site of the lymphocytic receptor and are able to stimulate the expansion of clones and their maturation in antibody-forming cells. The interaction of Ab2 β with the combining site of Ab1 is obligatorily antigen inhibitable, since Ab2 idiotypic is an antigen surrogate.
4. Ab2 ϵ (epibody) are antibodies which bind both to idiotypic and to an epitope of self or foreign antigen.

The major questions concerning the stimulatory effect of anti-Id antibodies are related to:

- The ability to distinguish Ab2 α or Ab2 γ from Ab2 β .
- The determination of the immunogenic and tolerogenic doses. If the idiotypes are surrogates of the antigens, then they may obey the same rules of immunogenicity as the antigens.
- The requirements of MHC-restricted recognition of internal image antigen.

Criteria that define Ab2

Several criteria have been proposed to distinguish Ab2 α from Ab2 β . Immunochemical criteria are based on the molecular mimicry concept, which are predicted that all Ab2 β resemble the antigen and therefore Ab1–Ab2 β interactions are antigen inhibitable. If this feature can distinguish Ab2 α from Ab2 β , it is not sufficient on its own to distinguish Ab2 β from Ab2 γ . This latter category is also antigen inhibitable but cannot elicit an antibody response to the antigen by itself.

The best criterion is a structural one. Ab2 β may share some amino acid sequence with the antigen. An

Figure 1 Various types of anti-idiotypic antibodies.

Ab2 β specific for anti-glutamic acid-alanine-tyrosine synthetic terpolymer (GAT), in which GT is the major immunodominant epitope, has a GTT surface-exposed tripeptide in the D region. The injection of this Ab2 β into animals elicits an anti-GAT or GT response. Similarly, an Ab2 β specific for anti-hemagglutinin reovirus antibody shares a tetrapeptide located in the CDR2 of the variable region of the light chain with the protective epitope of viral hemagglutinin. This antibody, as well as the synthetic peptide that corresponds to its shared sequence, can elicit an anti-viral immune response and can be recognized by cytotoxic T cells specific for viral hemagglutinin. It should be noted that Ab2 β , which mimic nonprotein antigens such as polysaccharides and glycolipids, and steroidal hormones such as aldosterone, have also been described.

Perhaps the most practical criterion for defining Ab2 β is the functional one; namely, their ability to elicit the production of Ab1 antibodies specific for the nominal antigen.

Immunization with anti-Id antibodies can, in principle, lead to the production of several types of antibody molecules: the Ag⁺/Id⁺/Ab1 type, which binds to nominal antigen and expresses the idiotype of the antibody used to prepare Ab2 β ; the Ag⁺/Id⁻/Ab1 type, which binds to nominal antigen but fails to express the idiotype of the Ab1 used as immunogen; and Ag⁻/Id⁺, which are Ab3 antibodies able to bind to the idiotype of Ab2.

In principle, the outcome of the immunization with Ab2 α or Ab2 γ antibody will be the activation of clones producing Ag⁺/Id⁺ and Ag⁻/Id⁺ antibodies, since these antibodies can interact only with Ab1 clones bearing the corresponding idiotypes or with Ab3 clones producing only anti-anti-id antibodies. In contrast, the outcome of the immunization with Ab2 β , which by virtue of its idiotypes could mimic the antigen will activate Ag⁺/Id⁺ as well as Ag⁻/Id⁻ clones, both of which are able to recognize the nominal antigen or its idiotypic surrogate. Obviously, Ab2 can also activate true Ab3 clones.

Therefore, the functional criterion which define an Ab2 β is the ability to initiate the production of antibodies specific for nominal antigens able to express a variety of idiotypes in the absence of the immunization with antigen itself.

Structural basis of internal antigen mimicry

Only the study of the three-dimensional structure of antigen-Ab1 (idiotype) and of Ab1 and Ab2 β was able to provide exhaustive information on the molecular basis of internal image immunoglobulin.

Fields *et al* determined the crystal structure of an idiotype and anti-idiotype to a resolution of 1.9 Å. Fv fragments were obtained from D1.3, a monoclonal antibody (mAb) specific for lysozyme, and from the E5.2 anti-idiotypic mAb. E5.2 exhibits the properties of an Ab2 β because when injected into BALB/c or C57BL/6 mice it elicits the production of anti-lysozyme antibodies.

Of the 18 residues of D1.3 that contact the anti-Id antibody and the 17 that interact with lysozyme, 13 were in contact with both lysozyme and the anti-Id antibody. The position of the atoms by which the anti-idiotype contacts the anti-lysozyme antibody are close to those by which D1.3 contacts lysozyme. The structural mimicry observed involves van der Waals forces, hydrogen bonds and solvent interactions.

Ban and colleagues determined the crystal structure of the Fab complex of a mAb specific for the E2 peplomer of feline infectious peritonitis virus and of an anti-Id antibody. This anti-Id also exhibited Ab2 β properties since when it was injected into animals it elicited the production of virus-neutralizing antibodies. The two Fab fragments interact by direct juxtaposition of their complementary CDRs. The CDR loops of the two Fabs were in contact through van der Waals forces and hydrogen bonds between 58 atoms of the virus-specific antibody and 59 atoms of the anti-Id. In total 19 residues of idiotype and 17 residues of anti-idiotype participate in the interaction. The CDR1 loops of the anti-Id light and heavy chains have a near identity with a hexapeptide of the antigen. These two regions of homology of the CDR1 of the light and heavy chain of Ab2 provide important contacts with the idiotype of the antibody specific for viral antigen.

These results indicate that the structural correlates of Ab2 β mimicry can be related to discontinuous determinants with contact residues located in various CDR loops. However, in other cases such as the feline peritonitis virus system some linear sequences located in CDRs can play a major role in antigen mimicry.

While there is a wealth of evidence that the surface Ig of B cells can recognize either discontinuous or linear epitopes on the native antigen, T cells recognize only peptides generated from the fragmentation of antigens which are then bound to self MHC antigens. This implicates that internal image-bearing peptides recognized by T cells are derived from immunoglobulin processed by antigen-presenting cells and selected by binding to either class I or class II major histocompatibility complex (MHC) antigens. The peptides associated with class I recognized by CD8 T cells are generally nonamers, whereas those associated with class II antigens recognized by

CD4 T cells are larger. Thus, an internal image immunoglobulin able to stimulate T cells should generate peptides identical to those generated by the processing of foreign antigens.

Practical applications of internal image idiotypes

In the early studies on idiotypic regulation, Eichmann and Rajewsky showed that polyclonal xenogeneic anti-Id antibodies of a particular isotype injected into mice can stimulate the production of antibodies against a polysaccharide antigen of streptococcus group A. Similar results have been obtained with monoclonal anti-Id antibodies in a hapten system, namely the activation of clones producing anti-TNP antibodies expressing 460Id.

Important information regarding the stimulatory aspect of anti-Id antibodies was provided by Hiernaux and colleagues, who showed that the injection of minute amounts of anti-Id antibodies after birth can expand silent clones. Knowledge of the expansion of silent clones was important for an understanding of the effect of anti-Id in tumor therapy.

However, Nisonoff and Roitt predicted that the idiotypic mimicry of foreign antigens can serve as a basis for the development of new vaccines based on the preparation of anti-Id antibodies. This hypothesis stimulated studies of the utilization of anti-Id antibodies as vaccines against bacterial, viral and parasitic antigens and was largely extended to other areas. An area in which anti-Id antibodies have seen practical application is tumor therapy both for lymphocytic tumors, in which the idiotypic functions as tumor-associated antigen, as well as solid tumors. In this case, the injection of antibodies against tumor-associated antigens can elicit the production of internal image, which expands the clones involved in anti-tumor immunity.

Other applications of internal image consist of the utilization of Ab2 β to identify or purify cell receptors for biologically active substances such as enzymes, hormones, or drugs. Anti-Id antibodies raised against antibodies specific for biologically active ligands will bind to the cell receptor and therefore permit its identification or eventual isolation.

The internal image concept has provided a theoretical basis for the practical application of anti-idiotypic antibodies in biology and medicine.

IDIOTYPE NETWORK

Constantin A Bona, Department of Microbiology, Mount Sinai Medical School, New York, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The idiotypic network theory formulated by Jerne views the immune system as being interconnected by idiotypes which are the antigenic determinants of variable regions of a lymphocytic receptor. Each receptor has several idiotypes which are collectively designated as its idiotypic.

The immune system is composed of lymphocytic clones that are able to recognize through their combining site (paratope) the foreign as well as the self antigens. The immune receptor of each clone expresses several idiotypes that are a special category of self antigens which can be recognized by other T or B cells bearing complementary paratopes. Operationally, the receptors recognizing the idiotypes are called anti-idiotypes or Ab2, whereas those expressing the idiotypes are called Ab1.

The idiotypes can be considered a special category of self epitopes which are autoimmunogenic without the need of breaking of self tolerance.

Background to the idiotypic network theory

The autoimmunogenicity of idiotypes was one of the first observations that led to the development of the network theory. This was first shown experimentally by the induction of an autoantibody response specific for idiotypic determinants borne by antibodies isolated from a rabbit and reinjected with its own antibodies several months later. Such rabbits produced antibodies able to bind to idiotypes of its own antibodies. The occurrence of autoanti-idiotypic antibodies was also demonstrated in physiological conditions during conventional immune responses elicited by an antigen.

A reciprocal fluctuation between Ab1 and Ab2 clones was observed in the immune response elicited by phosphocholine or inulin as well as in the florid and remission phases of certain autoimmune diseases such as systemic lupus or myasthenia gravis.

It should be pointed out that not all idiotypic (Id) determinants seem to be equally immunogenic. The dominant idiotypes that are expressed in high amounts in the circulation rarely cause anti-Id responses compared to individual or minor idiotypes. However, experiments carried out with animals in which the expression of cross-reactive idiotypes were suppressed after birth showed that such animals are able to produce anti-Id antibodies subsequent to injection with cross-reactive idiotypes.

These observations clearly show that all idiotypes are immunogenic but that the stimulation and/or proliferation of anti-Id clones depends on the concentration of idiotypes in the circulation.

Also contributing to the development of the idiotypic network theory were data that demonstrated that idiotypes are expressed on the immune receptor of lymphocytic clones; namely, the surface immunoglobulin of B cells or the TCR of T cells. These observations were of great importance for understanding clonal connectivity through idiotypes; namely, that the clones can speak one to another using an idiotypic dictionary that overlaps with the V gene repertoire of lymphocytes.

There is much data to demonstrate that there are lymphocytes in both B and T cell compartments able to recognize the idiotypes of B or T cell receptors. There is strong evidence that B cells are able to produce antibodies specific for the idiotypes of surface immunoglobulin of other B cells or for TCR of T cells. Similarly, in the T cell compartment it was shown that there are T clones able to recognize the idiotypic determinants of B cells (anti-idiotypic T cells) or of other T cell clones (Figure 1). Both CD4⁺ and CD8⁺ cells can recognize idiopeptides derived from the processing of V regions within the cytoplasm via the endogenous pathway. The idiopeptides resulting from the V region polypeptides are translocated to the membrane via the secretory pathway with either class I or class II major histocompatibility complex (MHC) antigens, where they are recognized by anti-idiotypic T cells. These two observations – namely, the autoimmunogenicity of idiotypes and the presence of idiotypes on the immune receptor of lymphocytic clones – represent the major contributions to the idiotypic network theory, which views the immune system as a web of V domains.

Figure 1 Symmetry of idiotypic recognition in B and T lymphocytic subpopulations.

An important question arising from this concept is whether or not all lymphocytes are idiotypically interconnected. There are two major categories of lymphocytes – short-lived and long-lived lymphocytes. Memory cells belong to the second category. Certain immunologists consider that the idiotypic network is predominant among the short-lived lymphocytes because these cells mainly produce multi-specific antibodies that can bind to both self and foreign antigen. However, there are data to suggest that autoanti-Id antibodies can only be detected against the idiotypes of antibodies produced during a secondary immune response, which are mainly the product of memory cells. Such secondary idiotypes are not detected during the primary response, which has been documented in the hen egg lysozyme system. Actually, the idiotypic network concept views the immune system as a dynamic process, which implies many types of interactions in the various stages of the development of an immune response as well as among the subpopulations of lymphocytes.

In the steady state, there is an equilibrium between Ab1 and Ab2. The major pattern of this equilibrium is the suppression of expansion of Ab1 clones by Ab2 lymphocytes. This probably represents an important physiological mechanism for the control of clonal homeostasis preventing the overwhelming of the immune system by certain clones, as can happen in the case of lymphocytic tumors.

When an organism encounters the antigen, the immune system decides which pathway should be taken – the suppressive or immune response. This is a transitional stage in which memory cells are generated, indicating that the immune system has the capacity not only of learning and deciding but also remembering the choice for a long time. In the transitional stage, this equilibrium is shifted by the antigen, which causes the expansion of Ab1 clones. In general, a reciprocal fluctuation between Ab1 and Ab2 clones is observed during this transitional state.

It is known that the antibody response, particularly against T dependent antigens, is associated with somatic mutations, a process believed to be crucial in the production of antibodies with high affinity. Somatic mutations can be important in establishing new idiotypic interactions and new regulatory patterns in the idiotypic network. Therefore, the transitional state that represents the immune response is determined by the clonal elements of the steady state as well as by variants which have been generated.

The system evolves toward a new steady state after the diminution of the immune response. However, this new steady state is qualitatively different, since it is associated with the generation of memory cells. The anti-Id antibodies that are produced during the

immune response can play an important role in the establishment of this new steady state. It is possible that an important fraction of anti-Id antibodies generated during the immune response carry the internal image of the antigen. These antibodies (termed Ab2 β) can persist in the body after the disappearance of the antigen and can contribute to the stimulation and survival of memory cells (Figure 2).

Postulates of idiotypic network theory

Idiotypic network theory is based on three major postulates:

1. The idiotypes of the immune receptor of lymphocytes are recognized within the immune system and they function both as links between clones and the target of regulatory processes.

Self-non/self discrimination is a central element of the clonal selection theory which views the immune system as a collection of clones programmed to recognize foreign antigens. While foreign antigens selectively induce the proliferation of clones bearing complementary immune receptors, self reactive clones are deleted or suppressed during ontogeny. In contrast, with the idiotypic network concept, the self/non-self discrimination ceased to be a central problem as the idiotypes that are self antigens are recognized and can be immunogenic. The major question of whether the immune system is directed outward (i.e. the recognition of foreign antigens) or inward (i.e. the recognition of self antigens) becomes meaningless.

Furthermore, there are a legion of experimental findings indicating that idiotypes are the target of regulatory processes. Both anti-Id antibodies or anti-idiotypic T cells can activate or suppress the expansion of clones bearing corresponding idiotypes. There are data to show that the maternal transfer of anti-Id antibodies via the placenta in the newborn, and of the injection of anti-Id antibodies in neonates and adults causes longlasting suppression of clones bearing the corresponding idiotypes. This suppression can be due either to a direct effect of anti-Id antibodies on the precursors or the generation of Id-specific suppressor cells. Maternally induced, neo-

Figure 2 Idiotypic interactions in steady-state and immune response.

natal or adult idiotype suppression generally requires a high concentration of anti-Id antibodies. In contrast, minute amounts of anti-Id antibodies exhibit a stimulatory effect. They can expand the dominant clones in place of the antigen or stimulate the expansion of minor and even silent clones. Antibodies specific for the idiotypic determinants of TCR can replace antigen in the stimulation or suppression of T cell clones.

It should be mentioned that not all serologically defined idiotypes are targets of regulatory processes. We defined a category of idiotopes – designated regulatory idiotopes – which are mainly involved in idiotype-determined regulatory processes. The regulatory idiotopes can be distinguished from conventional idiotopes by the following criteria:

- (a) They are autoimmunogenic.
- (b) They can be expressed on antibodies with various specificities.
- (c) They are recognized by regulatory T cells and could become dominant idiotopes.

The expression of regulatory idiotopes on antibodies with various specificities represents the structural basis of cross-regulation of clonal expansion by anti-Id antibodies. There are data which clearly show that the administration of anti-Id antibodies in minute amounts causes the activation of a clonally heterogeneous population with various antigen specificities and that the clones specific for nominal antigen (Ab1) represent only a fraction of the activated clones.

2. Idiotypes as internal image of the antigens.

This postulate is based on the idea that the idiotypes can mimic the foreign and self antigens. The idiotypes as markers of the variable region of immunoglobulin molecules or TCR can be envisioned as the negative imprint of the antigen. In contrast, the idiotype of anti-idiotype antibody can be seen as the positive imprint of the antigen. This postulate is not a simple consequence of the 'lock and key' principle of the interaction between an antigen and an antibody, but rather is based on molecular mimicry; namely, that the idiotype of a given antibody molecule can mimic the antigen. The concept of idiotypes as internal image of antigen indicates that the idiotypes represent links between the universe of foreign antigens and the immune system and that actually the immune repertoire is already primed by internal stimuli and therefore can promptly react to foreign antigen.

3. Through the self-recognition process, idiotypes can activate a cascade of complementary clones.

The concept is based on various experimental data which demonstrate that idiotypes can induce a chain of anti-idiotypic antibodies; namely, Ab1→Ab2 (anti-Id antibody)→Ab3 (anti anti-Id antibodies)→Ab4. Initially, the idiotype cascade was demonstrated experimentally in allotypically matched outbred rabbits, but later it was shown that it can happen in a single animal. The demonstration that the cascade can occur in a single animal strengthens the conclusion that the idiotype network is not a pure accident and has a precise functional role. Studies of the immunoreactivity of complementary anti-Id antibodies showed that Ab1 resembles Ab3 and Ab2 resembles Ab4. These data clearly show that the idiotype network is not open ended, as was initially thought and predicted by certain mathematical models.

The degeneracy of idiotype-anti-idiotype interactions within the cascade introduces a high degree of connectivity between lymphocytic clones and builds a complex web of reciprocal interactions. In fact, so-called Ab3 – which are produced subsequent to stimulation by Ab2 (anti-idiotypes) – are heterogeneous. They constitute a population of antibodies that cannot be distinguished from Ab1, a population that reacts with the idiotype of Ab2 (true Ab3) and, finally, a population that can exhibit a wide array of specificities (parallel sets).

Ontogenetic and phylogenetic significance of the idiotype network

The rearrangement of DNA segments encoding the specificity of the variable region of the immune receptor of T and B lymphocytes occurs during the development of these lineages. The V region genes are clustered in families. The members of the same family show a high degree of DNA homology. The DNA homology can be observed among certain V gene families of various species. Because the rearrangement of some V genes occurs during ontogeny before the expression of antigen receptor, it appears that the idiotype network does not play an important role in the establishment of the pre-immune repertoire. However, there is strong evidence to indicate that it plays an important role in the establishment of the primary repertoire in neonates and adults.

Maternal or neonatal idiotype suppression leading to ablation from the repertoire of the clones bearing the corresponding idiotypes is one of the best and most studied examples. Similarly, maternal anti-Id antibodies or idiotypes transferred via the placenta to neonates can play an important role in shaping the primary immune repertoire. For example, it was

shown that the injection of idiotype into mice during pregnancy stimulates the generation of idiotype-specific helper cells in neonates, which can expand silent clones to become dominant. Similar results can be obtained with anti-Id antibodies administered after birth. In physiological terms, it is advantageous for progeny to inherit the immune experience of the mother with an expansion of clones that are specific for common pathogens of a given species. This is particularly important in the period of postnatal life when the concentration of antibodies provided from the mother starts to decline.

The absence of an idiotype-induced expansion could explain the widespread epidemics and pandemics caused by pathogens that have not been encountered by previous generations, such as the pandemics caused by influenza viruses resulting from a major antigenic shift or the current human immunodeficiency virus (HIV) pandemics.

In certain cases, the maternal idiotypes can have deleterious effects. Thus, it is well known that an important fraction of newborns born to myasthenic mothers can develop transient symptoms of myasthenia due to the mothers' autoantibodies specific for acetylcholine receptors. However, in certain cases, the infants develop severe and chronic disease. It has been found that these patients produced anti-Id antibodies, which were probably responsible for the activation of autoreactive clones producing anti-acetylcholine receptor antibodies and which are involved in the pathogenesis of the disease. It is important to note that recent studies have shown that a relatively high fraction of the clones (about 7%) of neonates produce anti-Id antibodies and such antibodies can have either a stimulatory or suppressive effect. These observations clearly indicate that the idiotype network plays an important role in the establishment of the primary immune repertoire and that idiotypes or anti-idiotypes can act in lieu of the antigen in the fixation of the repertoire.

The immune response continuously generates clonal variants because of somatic mutations as well as the recombination of various segments of DNA during the rearrangement of immunoglobulin and TCR genes. The sequencing of V genes of antibodies specific for haptens and viral proteins has shown that each antibody has a different sequence from the germline V gene from which the rearranged V gene

was derived. This would imply that idiotype regulatory networks should exist for each clone. However, it has been shown that in each species there are regulatory patterns that are inherited. Despite the fact that each of the anti-arsonate antibodies in A/J mice are encoded by V_H genes that differ from the VH36-65 germline gene from which their rearranged genes derive, anti-Id antibodies specific for CRI of anti-arsonate antibodies will cause the suppression of the arsonate response in all A/J mice. This suggests that the idiotype network can play an important role during phylogeny in the elimination of variants that are not the subject of idiotype-determined regulatory processes and in the maintenance of the stability of the repertoire in a given species.

That the idiotype network is important both in selecting the initial available repertoire and in idiotype-determined regulation during immune responses elicited by both foreign and self antigens is a broadly held view based on a large number of experimental findings and clinical observations.

In the pro-B cell stage, the rearrangement of immunoglobulin heavy chain gene leads to the expression of surface membrane immunoglobulin (mIg μ). mIg μ assembles with Ig α -Ig β and surrogate light chains in pre-B cells, or conventional light chains in B cells, to form the precursor B cell receptor (pre-BCR) and B cell receptor (BCR), respectively. The pre-BCR is sufficient for the pre-B cell transition, and imposition of allelic exclusion. In the more mature B cell stages, specific recognition of antigen by the BCR triggers B cells for subsequent differentiation and proliferation into terminally differentiated plasma cells. Interaction of the Ig α /Ig β heterodimer with immunoglobulin heavy chains is essential for the signal transduction.

Protein tyrosine kinases are associated with BCR through the cytoplasmic tails of Ig α and Ig β

Ig α (CD79a) and Ig β (CD79b) are expressed prior to immunoglobulin heavy chain gene rearrangement and are the products of the mb-1 and B29 genes, respectively. The B29 gene contains six exons. In murine B cells, Ig α is about 34 kDa and Ig β is about 38 kDa. Both are extensively glycosylated and occur as disulfide-linked heterodimers, which are noncovalently associated with mIg. Both proteins are members of the immunoglobulin supergene family, each contains one Ig-like extracellular domain, a transmembrane spanning segment and a cytoplasmic tail. The cytoplasmic tails of Ig α and Ig β proteins contain a conserved sequence motif, which is called the immunoreceptor tyrosine-based activation motif (ITAM). Signaling through BCR induces a rapid sequence of phosphorylation steps. Upon receptor crosslinking, four members of the Src family of protein tyrosine kinases, including Blk, Lyn, Fyn and Lck, are activated to phosphorylate the Ig α and Ig β tails, causing the association of another tyrosine kinase, Syk, to the receptor. Syk contains two SH₂ domains, which associate with the conserved tyrosine residues in the ITAM motifs only when they are phosphorylated. This association results in the activation of Syk and augments transmission of the signal. Evidence that Ig α and Ig β couple the BCR to

intracellular protein tyrosine kinases comes from the following observations: 1) Ig α and Ig β exhibit low levels of tyrosine phosphorylation in resting B cells and are hyperphosphorylated in response to anti-Ig; 2) analysis of Lyn-deficient (Lyn^{-/-}) mice showed that the number of B cells decreased by half in the peripheral tissue due to the impaired proliferation; in addition, these B cells do not respond normally to a number of stimuli, including BCR crosslinking and CD40 ligand; 3) analysis of lymphoid cells from Syk-deficient (Syk^{-/-}) mice showed the total ablation of BCR signaling and blockage of the differentiation of B-lineage cells. The reconstitution of irradiated mice with Syk-deficient fetal liver revealed the importance of Syk kinase in pro-B to pre-B cell transition. Thus, Ig α and Ig β can couple B cell receptors to intracellular protein tyrosine kinases.

Ig α and Ig β mediate signals

At the immunoglobulin heavy chain locus, the rearrangement begins by the joining of diversity genes (D_H) with the joining elements (J_{H1}) and is followed by variable region (V_{H1}) gene rearrangement (V_{H1} → DJ_{H1}). Heavy chain gene assembly precedes light chain gene rearrangement. The ordered rearrangements of immunoglobulin heavy chain and light chain genes lead to the expression of surface immunoglobulin which is essential for B cell development. However, it has been shown that mIg μ molecules in which transmembrane polar residues have been mutated (Tyr-Ser:Val-Val, YS:VV) are unable to activate signal transduction. This disruption may be due to blockage of the association with Ig α and Ig β which comprise the signal transducer unit in each tail. In order to examine whether the pre-B cell transition and the inhibition of V-DJ joining is the result of signaling through the ITAM motifs of Ig α and Ig β tails, we generated an Ig μ transgene with the YS:VV mutation. In contrast to the wild type Ig μ transgene, B cells carrying the mutant transgene could not mediate allelic exclusion of endogenous loci. However, this mutant can be restored to wild type competence by addition of the cytoplasmic tail of Ig α and Ig β to the carboxyl terminus of Ig μ . Replacement of ITAM tyrosines in the Ig α and Ig β tail with phenyl-

alanine cannot restore this activity. These findings imply that allelic exclusion is mediated through signal transduction via Ig α and Ig β and is dependent upon intact tyrosine residues. To test whether Ig α and Ig β are required for the pre-B cell transition, strains of RAG $^{-/-}$ transgenic mice were created which carried a YS:V μ with or without the cytoplasmic domain of Ig α and Ig β . Mice carrying the mutant transgene could not produce pre-B cells. However, mice carrying the YS:V μ Ig α and Ig β chimera transgene developed pre-B cells. Thus, a single ITAM from either Ig α and Ig β is essential for the pre-B cell transition.

Since Ig α and Ig β are expressed at the pro-B cell stage, it has been postulated that an earlier checkpoint may be regulated by this signal transducer. In order to investigate the role of Ig α and Ig β at the pro-B cell stage, Ig β $^{-/-}$ mice were created by targeted gene disruption. These mice had normal levels of D $_H$ to J $_H$ rearrangement but V $_H$ to D $_H$ and V $_K$ to J $_K$ rearrangements were severely diminished. Since the B cells of these mice were arrested at the pro-B cell stage and did not express Ig μ , these mice failed to produce pre-B, mature B and plasma cells. These results revealed an independent role of Ig β outside the BCR in the pro-B cell stage.

D $_H$ to J $_H$ rearrangement has three reading frames (RFs). However, it has been shown that RF1 joints are overrepresented in functional murine heavy chains. This RF bias was considered to be due to the counterselection of RF3 on the bases of stop codons and of RF2 through the expression of the membrane-bound D $_{\mu}$ protein, since RF2 joining activates heavy-chain transcription from a previously inactive promoter 5' to D $_H$ and the resulting mRNA encodes a truncated μ protein, D $_{\mu}$. It has been proposed that D $_{\mu}$ may signal through Ig α and Ig β and activate the allelic exclusion of machinery which inhibits further VDJ recombination and suppresses the expression of functional Ig μ . Thus, cells containing D $_{\mu}$ will be arrested from further development. Results from the Ig β $^{-/-}$ mice showed that D $_{\mu}$ signaling is totally blocked and there was no bias against RF2 in D $_H$ joining. This revealed that the Ig α /Ig β signal transducer also plays a critical role in the counterselection against D $_{\mu}$. This finding is in accordance with the other observations that there is no counterselection in the absence of an Ig μ transmembrane exon, Syk, and λ 5. Taken together, these results suggest that the conserved ITAM motif in Ig α and Ig β tails couples the BCR to cytoplasmic tyrosine kinases which mediates signaling to the nucleus.

IgA

Brian J Underdown, Pasteur Mérieux Connaught Canada Research Centre, Department of Pathology, Faculty of Health Sciences, McMaster University, Hamilton, Ontario, Canada

Immunoglobulin A (IgA) is of special interest because of its predominance in exocrine secretions where it is thought to provide the host with a first line of immune defense against foreign microorganisms. The relatively high concentration of IgA in the exocrine secretions is due to two principal factors: 1) an enrichment in mucosal tissues of cells committed to IgA synthesis; and 2) the presence of a specific receptor on epithelial cells (poly-Ig receptor or pIgR) which transports newly synthesized polymeric IgA (pIgA) across the epithelium and discharges it into the secretory lumen.

Synthesis and distribution

IgA is found in species which emerged after the appearance of amphibia, although evidence has been presented that IgA-like molecules may exist in fish. In most higher vertebrates, the majority of IgA is synthesized by gastrointestinal lymphoid tissue, with smaller amounts synthesized at other mucosal sites such as the respiratory tract, salivary glands and reproductive tract. During lactation, mammary tissue contains substantial numbers of IgA-producing cells. The majority of these are thought to migrate from the gut, thus protective IgA antibodies generated by the mother against gastrointestinal organisms in the environment may be transferred to the infant via breast feeding. An important species variation should be noted: in addition to IgA, ungulates have even greater concentrations of IgG1 antibodies in milk, due to the presence in mammary epithelium of a specific receptor which transports IgG1 from blood to milk.

While much of the IgA produced by mucosal tissue is transported into the secretory lumen, some inevi-

tably enters the lymphatic circulation and is transferred to blood via the thoracic duct. In some species (e.g. rabbit, rat, chicken and mouse), polymeric IgA entering the blood is returned to the intestinal secretion via the liver, which, in these species, expresses the pIgR on hepatocytes.

The total quantity of IgA synthesized in humans has been estimated to be 66 mg kg⁻¹ day⁻¹, of which approximately two-thirds is derived from mucosal lymphoid tissue. The relatively large amounts of IgA synthesized daily may reflect the fact that the mucosal surfaces are constantly infected with organisms that are either commensal to the host or pathogenic. The bone marrow also provides an additional source of IgA, especially in humans.

IgA production is regulated by T cells. T cell-derived transforming growth factor β (TGF β) has been identified as the primary cytokine that promotes B cells to switch from IgM-bearing cells to IgA-bearing cells. Interleukin 5 (IL-5) has been identified as the major cytokine that drives the differentiation of IgA-bearing B cells to IgA antibody-secreting plasma cells.

Catabolism of IgA is thought to occur primarily in the liver. In humans, this appears to be mediated by the receptor for asialoglycoproteins, which targets by endocytosis, asialoglycoproteins to lysosomes.

Structure

The three-dimensional structure of IgA determined by crystallographic studies has not yet been reported. Consequently, there is still some uncertainty in the conclusions drawn from available data. However, computer models of IgA structure have been put forward based on analogy with the known three-dimensional structure of IgG.

The numbers of IgA isotypes vary between species. In humans, there are two isotypes (IgA1 and IgA2), whereas in rabbits as many as 13 have been reported. The principal difference between human IgA1 and IgA2 is the absence in IgA2 molecules of a 13 amino acid sequence in the hinge region, which is rich in proline, threonine and serine-containing O-linked glycosyl side-chains. This region is also the target of proteolysis by IgA1 proteases secreted by many bacteria which inhabit mucosal surfaces. In humans, the IgA2 isotype exists in two allotypic forms: IgA2m(1) and IgA2m(2). IgA2m(1) molecules also lack the cysteine in the heavy chain which links, through disulfide bonds, the α heavy chain to the light chain. In mice, the α chain is expressed as a single isotype and has been reported to exist in two allelic forms. BALB/c mice have IgA molecules that are similar to human IgA2m(1), in that their light chains are disulfide-linked to each other, rather than to the corresponding α heavy chain. IgA in the NZB strain contains the α chain cysteine which links α and the light chain by a disulfide bond. Allotypic variation also exists in the rabbit α chains. A diagram of the principal features of the human α_1 heavy chain of IgA is shown in Figure 1.

The advantage of the extended hinge region in IgA1 molecules has not yet been assessed but it could provide IgA1 molecules with greater segmental flexibility, compared with IgA2 antibodies, which in turn might enhance antigen binding of this isotype. This advantage might be offset by increased susceptibility of IgA1 molecules to attack by IgA1-specific proteases secreted by bacteria inhabiting the mucosal surface.

All α chains terminate in an octadecapeptide 'tail' sequence not found in the prototype immunoglobulin IgG. IgM also possesses a homologous extended tail at its C-terminus. IgA is secreted from lymphocytes as a four-chain 'monomer' subunit, as well as in polymeric forms consisting of dimers, trimers and tetramers. Polymer formation is accompanied by disulfide linkages between J chain (a 15 kDa protein synthesized by antibody-producing cells) and a cysteine present in the extended 'tail' as the penultimate residue of the α chain, at amino acid position 471.

Figure 1 The human α_1 heavy chain. h, Hinge region which is absent in α_2 chains; $\dagger$, O-linked carbohydrate; $\ddagger$, N-linked carbohydrate. The intrachain disulfide bonds within domains are shown above the line [SS]; other intrachain disulfide bonds and the interchain disulfide bonds are shown below the line. The cysteines at residues 311 and 471 are hypothesized to form an intrachain disulfide bond in IgA monomers and an intersubunit disulfide bond in dimeric IgA.

Figure 2 Secretory IgA dimer. The asymmetry of the disulfide bonds that form the dimer is emphasized. Disulfide bonding of the first domain of secretory component (N1) is shown linked to the $C\alpha_2$ domain, hypothesized to be at residue 311. (Reprinted with permission from Underdown BJ (1990) Transcytosis by the receptor for polymeric immunoglobulin. In: Metzger H (ed) *Fc Receptors and the Action of Antibodies*. Washington DC: American Society for Microbiology.)

Polymer formation confers on IgA enhanced avidity for binding antigen and is required for interaction of pIgA with the pIgR.

The arrangement of disulfide bonds joining the various subunits together in pIgA appears to be asymmetric. One model proposes that J chain is disulfide-linked through cysteine 471 to the two α chains of one monomer subunit. The two monomer subunits are then envisioned to be linked by the cysteines at position 471 of the monomer lacking J chain to cysteines in the $C\alpha_2$ domain (possibly residue 311) of the monomer which contains J chain. Formation of secretory IgA occurs with the addition of secretory component which, in humans, is known to be disulfide-linked to only one of the monomer subunits, presumably at residue 311. Dimeric secretory IgA is illustrated in Figure 2.

Function

The unique structural characteristics of secretory IgA provide some clues to its function. For example, the ability of polymeric IgA to bind to the pIgR and be transported to the mucosal secretions, coupled with

the relatively high proportion of plasma cells committed to IgA production at mucosal sites, provides the mucosal surface with substantial amounts of antibody. Being polymeric, secretory IgA has relatively high avidity for antigen, which should promote its antigen-binding function. The presence of secretory component appears to protect secretory IgA against proteolytic enzymes in the gut. Binding of secretory IgA antibodies to microorganisms would be expected to reduce the ability of the microbes to attach and enter the epithelium of the mucosae, two processes which seem crucial for the initiation of infection. Indeed, good experimental evidence exists to support this function of IgA. In addition to preventing attachment of microorganisms, secretory IgA is thought to perform an 'immune exclusion' function by combining with the myriad of soluble antigens in the diet, as well as those released from commensal and pathogenic flora, preventing them from entering the body. It has also been demonstrated that during its transcytosis through epithelial cells, IgA antibody comes into contact with, and neutralizes virus in infected epithelia.

Elimination of infectious agents from the mucosae may also involve cooperative interaction of IgA antibodies with other effector elements of the immune and inflammatory systems. For example, cells such as macrophages, neutrophils and eosinophils have been reported to have receptors which bind to various forms of IgA. Activation of the alternative pathway of the complement system by IgA has been demonstrated *in vitro*. The importance of these properties in combating infections at the mucosal surface is less evident, as it is not clear whether the relatively small number of inflammatory-type cells observed in the mucosal lumen are functional, nor is there evidence that an intact complement system exists at the mucosal surface or in external secretions.

The functional role of systemic IgA is not clear. Clearance of antigen in the form of antigen-IgA antibody complexes has been demonstrated and it is possible that this is particularly important in the case of antigens which have crossed the epithelial barrier into the circulation. This function would be expected to be carried out best by IgA antibodies induced by mucosal antigen.

Deficiency

In Caucasians, IgA deficiency is the most common form of selective Ig isotype deficiency. Estimates vary between 1:300 and 1:800 in a normal population. Among the Japanese, IgA deficiency is reported to be much less frequent. Individuals with IgA deficiency have normal α chain structural genes, but may

express a higher frequency of particular major histocompatibility complex (MHC) haplotypes. This suggests that IgA deficiency is associated with defects in immune regulation (e.g. secondary to cytokine deficiency) and evidence has been presented which indicates that IgA deficiency may be linked to the presence or absence of particular HLA haplotypes. In addition to generalized deficiency of IgA, selective deficiency in one or the other IgA isotype or in systemic versus mucosal IgA have been reported.

There appears to be general consensus that individuals with IgA deficiency are at risk for mucosal infection, although many such individuals are healthy. Individuals who develop a compensatory increase in IgM antibody synthesis appear to be indistinguishable from normal individuals with respect to frequency of mucosal infection. Infants who are transiently deficient in IgA in the first year of life are prone to develop atopic disease. An increased frequency of autoimmune diseases has also been reported in IgA-deficient individuals, which may reflect the importance of a putative defect in immune regulation, although increased exposure of the host to foreign antigens as a result of the loss of 'immune exclusion' may play a role. In contrast to humans, IgA deficiency has not been reported in many species. A group of IgA-deficient dogs has been reported.

Associated immunopathology

There are several diseases in which IgA is deposited in tissue in a pattern which suggests it may play a role in inducing pathology. For example, IgA nephropathy is one of the most common Ig-associated nephropathies. Typically, deposits which consist primarily of IgA1, often together with components of the complement alternative pathway, are found in the renal mesangium. While there have been a large number of studies *in vitro* indicating the potential of IgA to activate the alternative pathway of complement, only a few have used antigen-antibody complexes in which the antigen did not have the potential to activate the complement system in an aggregated form. However, some studies have avoided this pitfall and it appears that IgA has the capacity to activate the alternative pathway with less efficiency than IgG. The association of mucosal infection with either the onset or exacerbation of IgA nephropathy gives further credence for the pathogenic role of IgA in this disease. It should be noted that IgA nephropathy is a disease with a broad clinical spectrum and, in approximately half the patients, IgG and IgM are also observed associated with IgA deposited in the renal mesangium. These data raise the possibility that these latter isotypes are required

to produce a more severe clinical course. Dermatitis herpetiformis is a disease characterized by deposition of IgA at the dermal–epidermal junction. Here again, components of the alternative pathway of complement are deposited along with IgA. Dermatitis herpetiformis is often associated with elevated levels of gliadin-specific antibodies and the clinical course of some patients may be reduced by a gluten-free diet. A bullous disease of childhood has been described in which linear deposits of IgA are detected along the basement of affected subepidermal areas, suggestive of the deposition of specific anti-basement membrane IgA antibodies.

Induction of IgA responses

Immunization at mucosal surfaces is known to be the most effective method for inducing IgA antibody responses. Migration of IgA-committed cells to other mucosal sites is known to occur, but sufficient protection of these sites probably requires expansion of seeded cells by direct application of antigen to the secondary sites. Parenteral immunization also results in a brief synthetic boost of pIgA in blood, the function of which is not known; however, there is evidence that parenteral priming will seed mucosal sites for IgA production to a secondary mucosal challenge with antigen.

To date, immunization at mucosal surfaces is accomplished best by living organisms, followed by mucosal adjuvants such as cholera toxin. Nonliving antigens are, in general, not effective unless targeted to Peyer's patches.

IgD

Benvenuto Pernis, Department of Microbiology, College of Microbiology, College of Physicians and Surgeons of Columbia University, New York, USA

The IgD immunoglobulin isotype was discovered in 1965 by Rowe and Fahey, who found a human myeloma protein with unusual properties. They also found small amounts of immunoglobulin of the same type in normal human serum. Subsequently, immunoglobulins that could be generally defined as IgD were found in all mammalian and avian species. This evolutionary conservation points to a defined functional role of this immunoglobulin, yet, after a third of a century of intensive investigation the specific function of IgD, as distinct from the other immunoglobulins, remains to be defined.

The protein

Human IgD is a monomer of 175 kDa with 9% carbohydrate. The human heavy chain (δ) has three domains and an unusually long hinge region that is highly sensitive to proteolysis. The murine δ chain is shorter and is missing a domain corresponding to the human C_δ2. The membrane form of the δ chain has in addition a transmembrane domain and a short intracytoplasmic extension with the sequence Lys-Val-Lys, analogous to that of the membrane form of the μ chain.

The gene

The gene that codes for the constant portion of the δ chain is located downstream of the μ gene. In the mouse it consists of three exons ($C_{\delta}1$, $C_{\delta}2$ and $C_{\delta}3$) that code for the body of the δ chain, plus three small exons that code for the C-terminus of the secreted (δs) or the membrane form of the δ chain ($\delta M1$ and $\delta M2$); all these are separated from $C_{\delta}3$. It is noteworthy that there is no switch region upstream of $C_{\delta}1$. The simultaneous synthesis of μ and δ chains, with the same variable region, by one given B cell occurs by the production of a transcript that includes both the μ and the δ genes, followed by alternate splicing to produce separate μ and δ mRNAs. When B cells mature to an IgM-secreting plasma cell, transcription usually stops after the μ gene and therefore the δ message is not included in the transcript. Alternatively, when the B cell matures to an IgD-secreting plasma cell (a relatively rare event), the μ gene is deleted.

Serum IgD

In humans, serum IgD levels vary from 3 to 40 $\mu\text{g ml}^{-1}$, with some relationship to the Gm type of the individual. These low IgD levels are the product of IgD plasma cells that are found in low numbers in the spleen and, more frequently, in the tonsils. The low numbers of IgD plasma cells in the lymphoid tissues, together with the short half-life of the immunoglobulin (2.8 days), explain the low levels of IgD in the serum. The relative paucity of IgD plasma cells also explains the rarity of IgD myelomas. Similar conditions are also found in mice, in which there are two IgD allotypes, termed Ig5^a and Ig5^b.

It is curious that no specific antibodies have been found so far in serum IgD, even after immunization, even though humans exposed to chronic antigen stimulation tend to express relatively higher serum IgD levels. Conversely, no specific effector function has been ascribed to the IgD isotype. Another curious finding with human serum IgD, but not membrane IgD, is that it is more commonly associated with λ than with κ light chains; similarly, human IgD myelomas with λ chains are about five times more frequent than those with κ chains.

Membrane IgD

In sharp contrast to the low levels of serum IgD, both in humans and in mice, IgD is expressed on the membrane of the majority of B lymphocytes. In mice, membrane IgD appears around the end of the first week postpartum, and the percentage of B cells with

membrane IgD then rapidly increases, more or less in parallel with the maturation of the T cell system of the animal. However, δ chains that are not expressed on the membrane are apparently synthesized quite early in developing B cells. A completely rearranged δ gene causes allelic exclusion in transgenic mice.

Membrane IgD and IgM molecules, with the same V_H and with the same light chain, and therefore with the same antigen-binding site, are expressed together on the majority of B lymphocytes. Since μ and δ chains do not pair, there are no hybrid μ/δ molecules. The ratio between the two isotypes may vary between high δ /low μ and the reverse; it may be rather stable in some cells, like the Ly1-B cells, that are low δ as a rule, or it may be variable even in single clones of B cells, like some human Epstein-Barr virus (EBV)-transformed cells where it has been found to vary between the two extremes in the same clone. The ratio of IgM to IgD on a given B lymphocyte must have functional consequences that are not as yet totally clear; it is established, however, that membrane IgD is reduced in memory B cells and that it disappears with the process of maturation to plasma cells.

After cross-linking with anti- δ antibodies, membrane IgD is internalized by the cells, much in the same way as the other membrane immunoglobulin isotypes; however, in some B cell lines, differences in the intracytoplasmic location of the IgD/anti-IgD complexes versus the IgM/anti-IgM complexes have been observed; this difference may have relevance to the role of the two isotypes in the processing of antigens by B lymphoid cells.

Membrane IgD molecules are associated with a heterodimer consisting of two proteins of 35 kDa (IgD- α) and 39 kDa (IgD- β); the presence of the IgD- α chain is necessary for the membrane expression of IgD. Membrane IgM is also associated with a heterodimer formed by the same IgD- β chain discussed above and by an IgM-specific IgM- α chain of 34 kDa. Thus the two membrane immunoglobulin isotypes are associated with companion molecules which are related but different; these biochemical observations may go a long way toward the understanding of the function of the two classes of antigen receptors that coexist on the membrane of B lymphocytes.

So far, however, no gross differences have been detected between the biochemical events that take place in B cells after cross-linking IgM and those seen after cross-linking IgD; therefore, the immediate signals given to the B cell by the two classes of antigen receptors seem to be equivalent.

However, a difference in the kinetics of phos-

phorylation of the protein tyrosine kinases after cross-linking of IgM and IgD with the same antigen specificity has been detected by Kim and Reth. In IgM-expressing cells phosphorylation reaches a maximum in 1 min and decreases after 60 min, whereas in IgD cells the phosphorylation of the protein kinases reaches a maximum in 60 min and persists longer than 240 min after exposure to antigen. This may be relevant in conditions where the B cells are competing for antigen, as in the germinal centers.

The function of IgD

Notwithstanding a long series of experiments and hypotheses, the immunological function of IgD is still far from being completely understood. Many of these experiments were performed with heterologous or allogeneic anti- δ antibodies administered *in vivo*. The early ones were performed on monkeys using rabbit antihuman IgD antisera that cross-react with monkey IgD. The result was a marked polyclonal stimulation of immunoglobulin production, mostly of the IgG class, that included several antibodies to the different serum proteins of the heterologous anti-IgD antiserum. The mechanism of this marked reaction, that developed in a couple of weeks after the injection of the antiserum, was not clarified. With the isolation of murine IgD from a myeloma, and with the availability of purified hetero- or alloantimouse IgD antibodies, the study of the effect of administration of anti-IgD *in vivo* could make considerable progress.

Finkelman and coworkers have clearly shown that the polyclonal stimulation of B cells induced by heterologous anti-IgD, that eventually results in the production of IgG1, takes place in two stages, of which the first is T independent; the second involves T helper cells, activated by the heterologous immunoglobulins, that help the IgD⁺ cells to mature, switch to IgG1, and secrete the latter. The simplest interpretation is that B cells bind anti-IgD, process this foreign molecule, and present its fragments to T helper cells specific for it. However, this interpretation is not the only one. In fact, experiments with transferred congenic B cells of different allotype also point to the possibility that B cells activated by anti-IgD can use in a nonspecific fashion the large amount of cytokines produced by the activated T helper cells. This last possibility would be in agreement with the production of specific antibodies observed in the early experiments conducted with monkeys, that, as already noted, suggested an 'adjuvant' effect of the injection of heterologous anti-IgD antibodies.

It is clear, however, that protein ligands bound to membrane IgD can be processed very efficiently for

presentation to T cells. Another possible interaction between IgD and T cells is through a receptor for IgD that is present on the membrane of a subpopulation of T cells; through this receptor IgD can stimulate T cells in a nonspecific fashion.

Double transgenic mice, which express both the gene for hen egg lysozyme (HEL) and the genes for a high-affinity anti-HEL antibody; are tolerant to HEL but contain high numbers of B cells with anti-HEL membrane Ig that is IgD and not IgM. Since tolerance to the antigen cannot be explained by suppressor T cells, it appears that this is somehow an intrinsic property of the IgD⁺ B cell population. IgD may therefore have a role in B cell tolerance. Curiously, such a role may favor tolerance, a view opposite to that entertained previously, when the observation that membrane IgD in murine B cells appeared after expression of IgM seemed to favor the interpretation that IgD could prevent B cell tolerance.

Interesting observations that shed some light on the function of membrane IgD have been made by Roes and Rajewsky in mice in which the δ gene had been knocked out. In heterozygous $\delta^{+/-}$ mice the wild-type IgH locus was considerably overrepresented amongst the peripheral B cells and in particular in cells producing IgG1 in response to a T-dependent antigen. In homozygous IgD-deficient mice affinity maturation of antibodies in a primary T cell-dependent response is delayed. This is again consistent with a role of the IgD receptors where the B cells are competing and are being selected for receptor affinity, such as in the germinal centers.

IgE

Hannah J Gould and **Rebecca L Beavil**, The Randall Institute, King's College London, London, UK

IgE (immunoglobulin E) is the least abundant, but in many respects the most potent, of the various antibody classes found in mammals. In normal individuals the concentration of IgE in serum (100 ng ml^{-1}) is 10 000 times less than that of IgG (15 mg ml^{-1}), but it is elevated in allergic individuals, in certain parasitic diseases (e.g. schistosomiasis) and in the hyper-IgE syndrome. The designation IgE stems from the observation that injection of this antibody into skin, followed by antigen at the same site, causes passive cutaneous anaphylaxis, characterized by the appearance of a wheal (edema) and flare (erythema) reaction at the site of the injections. Erythema ensues when antigen crosslinks IgE antibody bound to the high-affinity IgE receptor on skin mast cells, which leads to the release of agents, such as histamine, that cause vasodilatation and pooling of blood in the tissue. This is part of the typical inflammatory reaction caused by immune processes involving IgE antibodies and mast cells (see below). IgE is best known for its association with allergy, and individuals with abnormally high serum concentrations of IgE are said to be 'atopic'; however, epidemiological and experimental evidence suggests that IgE antibodies may have a beneficial function in the rejection of parasites.

Structure of IgE

Like antibodies of any other class, IgE is composed of four polypeptide chains, two heavy chains and two λ or κ light chains; its main features are described in Table 1. IgE is characterized by its ϵ heavy chains, which have four invariant or constant (C) region domains, C ϵ 1–C ϵ 4 (Figure 1), corresponding to those in the μ chain of IgM (C μ 1–C μ 4), but differing from the three that occur in the γ - δ - and α -heavy chains of IgG, IgD and IgA, respectively. The extra domain is C ϵ 2 (or C μ 2 in IgM), which occupies the equivalent position to the hinge found in IgG, IgD and IgA. IgE can be proteolytically cleaved into Fab and Fc fragments in the same way as IgG. The cleavage site lies between C ϵ 1 and C ϵ 2, and thus the Fc fragment has three (C ϵ 2–C ϵ 4) rather than two (C γ 2 and C γ 3) immunoglobulin domains per chain. The homology between the C ϵ 3–C ϵ 4 region of IgE and the IgG Fc, and the existence of a high-resolution crystal structure of the IgG1 Fc, has provided the basis for a model of this region of the IgE structure (Figure 1).

IgE is heavily glycosylated, the carbohydrate contributing 13% of the total mass. There are seven putative glycosylation sites, three in the C ϵ 1 domain of the Fab and four in the Fc region. The latter include the conserved site in C ϵ 3 (Asn397; homolo-

Figure 1 Structure of IgE. Each of the immunoglobulin domains is represented by rectangles. Intrachain and interchain disulfide bridges are represented by S-S, and external glycosylation sites are shown as black circles. Also shown is the α -carbon backbone trace of the C_ε3 and C_ε4 domains, modeled on the homologous IgG1 structure, with the conserved internal (buried) carbohydrate between the two C_ε3 domains.

gous to Asn297 in C_γ2), which is buried between the two ϵ chains in the model of IgE (Figure 1), and three additional sites (Asn265 in C_ε2 and Asn383 and Asn371 in C_ε3), which should be exposed on the surface of IgE. Two of these, Asn371 and Asn383, however, do not appear to be fully occupied.

The crystal structure of IgG does not allow prediction of the structure of C_ε2 or of its disposition with respect to C_ε3, but X-ray scattering data on the IgE-Fc suggest that there is a sharp bend between these domains. This is consistent with evidence from fluorescence energy transfer experiments, which indicates that IgE is bent in solution and remains so when bound to its high-affinity receptor (Figure 2).

Receptors for IgE

There are two cell surface receptors for IgE: FcεRI and FcεRII (also known as CD23). Their properties are set out in Table 2.

FcεRI comprises four polypeptide chains: one α , one β and two γ chains (Table 2). Only the first possesses an appreciable length of extracellular sequence; this contains two immunoglobulin-like domains and can be modelled on the nuclear mag-

Figure 2 IgE adopts a bent conformation in solution. The immunoglobulin domains of IgE are represented by ellipses, and are arranged in a conformation compatible with available structural data. Also indicated is the measurement between the ends of the molecules as determined by fluorescence energy transfer methods; the diagram is to scale.

netic resonance and crystal structures of two homologous proteins (CD4 and CD2). It is known to form the binding site for IgE. The other three chains have more extensive intracellular sequences and are responsible for signal transduction. The affinity of FcεRI for IgE ($K_A \sim 10^{10} \text{ M}^{-1}$) is at least 1–2 orders of magnitude higher than that of any other Fc receptor–antibody interaction. FcεRI forms a 1:1 complex with IgE, attaching to one or both of the C_ε3 domains. C_ε4 sequences, however, are required for binding with full high affinity, probably because of their influence on the structure or disposition of the C_ε3 domains. The activities of FcεRI are a function of the cells in which it is expressed, and include IgE antibody-dependent antigen presentation in Langer-

Table 2 Characteristics of IgE receptors FcεRI and FcεRII

Feature	FcεRI	FcεRII
Structure		
Alternative names	High-affinity IgE receptor	Low-affinity IgE receptor, CD23
Cellular distribution	Mast cells, basophils, eosinophils, Langerhans cells, activated monocytes	B Cells, T cells, platelets, macrophages, natural killer (NK) cells, follicular dendritic cells, eosinophils, epithelial cells
Subunit composition	One α, one β and two γ chains	Homotrimer, cleaved to soluble fragments
Transmembrane regions	α = 1, β = 4, γ = 1 (×2), total = 7	1 per monomer, total = 3
Orientation	Intracellular C-termini	Intracellular N-terminus
Structural motifs	α = two immunoglobulin domains	C-type animal lectin, α-helical coiled coil, reverse RGD (Arg Gly Asp) adhesion sequence
Post-translational modification	Seven N-glycosylation sites in α, Ser, Thr, Tyr phosphorylation in α	Single N-glycosylation site
Affinity for monomeric IgE	$K_a \sim 10^{10} \text{ M}^{-1}$	$K_a \sim 10^7 \text{ M}^{-1}$
Binding site on IgE	C _ε 3	C _ε 3
Binding site on receptor	α Chain, membrane proximal Ig domain	Lectin domain; all soluble fragments bind
Function	Degranulation of mast cells	Growth and differentiation factor for hematopoietic cells; rescues germinal center B cells from apoptosis; IgE antibody dependent antigen presentation; regulation of IgE expression; IgE antibody dependent cellular cytotoxicity (ADCC)

hans cells and a wide variety of effector functions in mast cells, basophils, macrophages, eosinophils and platelets.

FcεRII/CD23 is a type II integral membrane protein (cytoplasmic N-terminus), which occurs in two forms, the a-form and the b-form, differing by 6–7 amino acids at their N-termini. The former is constitutively expressed in activated B cells and the latter is upregulated by interleukin 4 (IL-4) on a variety of cell types. FcεRII/CD23a mediates IgE antibody-dependent presentation of antigen to T cells and FcεRII/CD23b the phagocytic activity of macrophages. The IgE-binding portion of FcεRII/CD23 is a C-type (Ca²⁺-dependent) lectin domain, differing from other known Fc receptors expressed on cell membranes, all of which utilize immunoglobulin domains. The lectin domain is near the C-terminus of the protein, which lies at the distal end of the extracellular sequence. Separating this domain from the transmembrane sequence is a region that forms an α-helical coiled-coil stalk, responsible for the association of FcεRII/CD23 into trimers in the cell

membrane. FcεRII/CD23 is cleaved by endogenous proteases into fragments with important cytokine activities, not least of which is in upregulation of IgE synthesis via complement receptor 2, also known as CD21. Binding of IgE protects FcεRII/CD23 from such fragmentation. The membrane-bound form of FcεRII/CD23 is involved in feedback regulation of IgE synthesis.

A third protein, galectin 3 (also known as ε-binding protein or ε-BP), an S-type lectin, binds to IgE (and indeed to FcεRI), recognizing carbohydrate chains, and may be another modifier of the IgE response.

Control of IgE synthesis

IgE is distinguished from other antibody classes (IgM, IgD, IgG and IgA) by its ε heavy chains. The heavy chain immunoglobulin gene cluster including the gene segments encoding the constant region of the ε chain (C_ε) are found on chromosome 12 in mouse and chromosome 14 in humans. The antigen

specificity of a B cell clone is determined by the formation of a functional μ heavy chain gene, following the productive recombination of variable (VDJ) and C_μ gene segments. Association with light chains then results in the expression of IgM (and IgD) in the cell. Upon appropriate stimulation of the B cell, the rearranged gene may then undergo further rearrangement within the heavy chain gene cluster, resulting in apposition of the same VDJ sequence to the C region encoding an antibody of a class other than IgM. Heavy chain switching may be directed to C_γ (for IgG), to C_ϵ (for IgE) or to C_α (for IgA), which all lie downstream of C_μ , and is a necessary step in the expression of the new antibody class, with its characteristic effector functions. IgG, IgE and IgA are recognized by class-specific Fc receptors on different types of cells, which have different tissue distributions and distinct functions in immunity.

The mechanism of heavy chain gene switching is partially understood. Upstream of each of the C cassettes are two important sequences, the so-called I exon and the switch or S region. The selection of C_γ , C_ϵ or C_α is determined by the exposure of the B cell to particular cytokines: interferon γ for three of the four IgG subclasses, IL-4 or IL-13 for IgE and the fourth IgG subclass (IgG1 in mouse, IgG4 in humans), and transforming growth factor β for IgA. These cytokines act by inducing the expression of germline gene transcripts, initiated upstream of S and terminating beyond the C cassette. The germline gene transcript is spliced to form a transcript with a germline exon, I, and the exons in the C cassette. This transcript cannot be translated because it contains multiple stop codons in the I exon. This exon is looped out and lost when VDJ recombines with C to form the switched gene.

The direction of heavy chain switching is determined by the microenvironment of the B cell. IL-4 is produced by activated T_H2 cells and mast cells. When B cells present antigen to T_H2 cells, they induce IL-4 secretion and expression of CD40-ligand (CD40L), which provides the second signal required for heavy chain switching. This process occurs in lymphoid tissue, and also elsewhere (even *in vitro*) if B cells, IL-4 and a CD40L, such as an antibody to CD40, are present in the medium. Figure 3 shows how the release of IL-4 upon the degranulation of mast cells might stimulate a T_H2 response. The differentiation of T_H0 cells to T_H2 cells is stimulated by IL-4, first from an exogenous source, in this case mast cells, and later in an autocrine fashion. Antigen presentation to T cells via MHC II (major histocompatibility complex class II), following internalization of antigen-IgE complexes, bound to Fc ϵ R/CD23, activates the T cells to secrete IL-4 and express

CD40L, thus stimulating heavy chain switching to IgE in the B cell. Antigen stimulation of B cells, soluble fragments of Fc ϵ R/CD23 and IL-6 are perhaps further required for differentiation of the B cells into plasma cells which secrete IgE.

Several factors are known to stimulate the growth and differentiation of B cells in an IgE class-specific manner. Three of these (EBV, soluble fragments of Fc ϵ R/CD23, and anti-CD21) are ligands for CD21, expressed on the surface of B cells. The original name of this protein, complement receptor 2, reflects the function of CD21 as the receptor for the activated products of the third component of complement, C3. These have the effect of lowering the threshold antigen concentration for clonal selection of B cells. Fc ϵ R/CD23 apparently stimulates IgE synthesis by a mechanism analogous to that by which C3 stimulates the synthesis of specific antibodies; this involves upregulation of the 'survival gene' Bcl-2 in the cell nucleus. Accordingly, both C3 and Fc ϵ R/CD23 may effect clonal selection by preventing apoptosis (cell death) and so permit cell proliferation. Interestingly, while C3 promotes specific antibody synthesis, Fc ϵ R/CD23 stimulates IgE synthesis, regardless of the specificity of the antigen receptor.

Figure 3 illustrates how IgE is switched on, but it does not reveal how this positive feedback mechanism is controlled to set an upper limit to the concentration of IgE. The properties of the Fc ϵ R/CD23 knockout mouse demonstrate that Fc ϵ R/CD23 is important in the downregulation of IgE synthesis, though it does not exclude an additional upregulatory function, as explained below. *In vivo* inhibitory mechanisms should operate at IgE concentrations above the K_D for the IgE-Fc ϵ R interaction; the relatively low affinity of Fc ϵ R/CD23 for IgE (compared with Fc ϵ R) may thus be inseparable from this function. IgE synthesis is inhibited by the binding of IgE, or, better, antigen-IgE complexes, to Fc ϵ R/CD23 in the B cell membrane. Presumably, the greater efficacy of the antigen-IgE complexes results from their ability to crosslink Fc ϵ R/CD23 molecules in the B cell membrane, and thereby deliver a negative signal to the cell. An analogous mechanism for feedback inhibition by IgG, involving a low-affinity IgG receptor, has been studied in greater detail with regard to the signal transduction pathway.

The activity of Fc ϵ R/CD23 in both upregulating and downregulating IgE synthesis may be explained by the fact that it is cleaved at the cell membrane by endogenous proteases into fragments that stimulate IgE synthesis by binding to CD21, as described above. But IgE binding to Fc ϵ R/CD23 inhibits proteolysis, and thereby prevents the release of the stimulatory fragments. Moreover, crosslinking of

Figure 3 Synthesis of IgE. Simplified diagram of the mechanisms and key molecules involved in B cells switching to IgE after exposure to allergen. On binding to allergen, IgE interacts with its high-affinity receptor on mast cells, causing the cells to degranulate and release histamine, lipid mediators and IL-4. The IL-4 stimulates T_H0 cells to become T_H2 cells expressing IL-4. In addition, IgE–allergen complexes bind and crosslink CD23 (FcεRII) on B cells expressing surface IgM. The allergen is then internalized, processed and presented on the cell surface by class II MHC. The MHC–allergen complex is then recognized by the TCR on the T_H2 cells, and this cell–cell contact induces the expression of CD40L on the T_H2 cells, which then binds to CD40 on the B cell. This signal, in conjunction with the IL-4 produced by the T_H2 cells, induces switching and differentiation of the B cell, ultimately into either a memory B cell or a plasma cell secreting IgE.

FcεRII/CD23 by antigen-IgE complexes delivers a negative signal to the cell. Therefore, FcεRII/CD23 stimulates IgE synthesis at low IgE concentrations and inhibits IgE synthesis at high IgE concentration: it is pivotal in the regulation of IgE.

Biological functions of IgE

The biological function(s) of IgE in cellular immunity can be related to its partnership with the high-affinity receptor, FcεRI, on mast cells and Langerhans cells. Its interactions with the same receptor on eosinophils and monocytes are undoubtedly important also, but their significance is still somewhat obscure. Langerhans cells are bound in the epithelium and are thus favorably placed for the capture and processing of antigens recognized by IgE antibodies bound to FcεRI. Following antigen capture the cells travel through the circulation to lymphoid tissues, where they stimulate T cells with specific receptors. Mast cells are distributed throughout the mucosa of tissues lining the skin, lungs and gut (major organs affected by allergic disease). When multivalent antigens bind to IgE antibody-sensitized mast cells and crosslink the receptors, several processes ensue: 1) the cell degranulates, causing release within minutes of histamine and other stored mediators of inflammation, including the potent cytokines, IL-4 and tumor necrosis factor α (TNF α); 2) lipid mediators are synthesized and released (also within minutes); and 3) several genes encoding inflammatory cytokines, including IL-4, IL-5, IL-6, IL-13, granulocyte-macrophage colony-stimulating factor and TNF α are activated (over a period of many hours). The local high concentrations of the mediators and cytokines leads to: 1) vasodilatation; 2) increased capillary permeability, causing the leakage of macromolecules and cells into the tissues (which results in the edema, referred to above); 3) airway smooth muscle contraction (which impedes entry of further airborne antigens to the lungs) and bowel movement (to expel parasites); and 4) upregulation of adhesion molecules (e.g. ELAM, VCAM-1 and ICAM-1) on endothelial cells lining the tissues, which results in the recruitment of inflammatory cells (notably, T cells, eosinophils and macrophages). These conditions initiate a 'leukocyte cascade' or inflammatory response, centering on the sites of antigen provocation. The allergic response is divided into two phases, an 'immediate' response, termed 'type I hypersensitivity' in the medical literature, and the 'late phase response', or subsequent inflammatory reaction.

It has long been thought that localised anaphylaxis evolved in mammals to enable them to eliminate parasites, but that it has become largely deleterious

in humans, since, at least in allergic individuals, it is triggered by innocuous substances and is then manifested as allergy. It must be kept in mind, however, that parasites such as *Schistosoma mansoni* are endemic in many parts of the world and epidemiological (if not experimental) evidence suggests that IgE is protective. It is also possible that this response, essentially unique to the IgE antibody class, has as yet undiscovered functions.

On the whole, allergy is a concern in the more highly industrialized parts of the world, where immunology is mainly practised and where intensive efforts are being made to understand the 'pathogenesis' of allergy. Allergic conditions include hayfever or rhinitis (the most common), asthma, atopic dermatitis, food allergy and allergic uveitis (affecting the eyes). Anaphylactic shock is the only manifestation of the response that is systemic in nature, and thus differs from the others, which predominantly affect single organs. There has been an alarming increase, corresponding to a 10-year doubling rate, in the incidence of allergic disease in the industrialized parts of the world over the last few decades. Now one in five adults suffers from some form of allergy and a similar proportion of children suffer from asthma. IgE is implicated in the pathogenesis of allergy, as a key component in both the afferent (by way of dendritic cells and B cells) and the efferent (by way of mast cells and basophils) limbs of the immune response. The reasons why some individuals, but not others, are predisposed to this outcome are not well understood.

IgG

Robert H Painter, Department of Biochemistry, University of Toronto, Toronto, Canada

Immunoglobulin G (IgG) is the simplest, most abundant antibody class in vertebrates constituting some 75% of total immunoglobulin in humans. These molecules are glycoproteins formed of four polypeptide chains, consisting of two identical copies of each of two kinds of polypeptide chain: light (L) (which may be of either the κ or λ class), and heavy, gamma (γ) (which may be of one of four subclasses), linked together by disulfide bonds and noncovalent forces in the form L–H–H–L. Individual immunoglobulin G molecules will differ in their amino acid sequence but within an IgG molecule the two L chains are identical and the two H chains are identical to each other, a consequence of the fact that only one L chain gene and one H chain gene is expressed in any antibody-producing cell. The function of the molecule is to effect a liaison between antigen and the effector systems of the body. It is a multifunctional molecule, bivalent with respect to antigen, structurally differentiated with the antigen-binding sites at one end, one in each Fab, and a variety of sites for engaging non-specific effector functions in the Fc region of the molecule.

Structure

Internal sequence homologies provided the first indication that the L and H polypeptide chains fold into discrete and independent domains, each consisting of about 110 amino acids and containing a 60 residue disulfide loop. This has been confirmed by electron microscopy and X-ray diffraction analysis. The domains are numbered from the N-terminus: V_L and C_L (κ or λ) in the case of the light chain, and V_H and C_H1 , C_H2 and C_H3 in the case of the heavy chain. The V or variable domains show extensive sequence variation associated with their antigen-binding specificity, while the constant domains exhibit only subclass (isotypic) and allotypic variation in amino acid sequence. There are four subclasses of the heavy (γ) chains and there are allotypic variations within these subclasses (Table 1).

The mid-section of the γ chain is characterized by a region of extended polypeptide chain known as the hinge region. Its purpose seems to be to extend the molecule and to facilitate segmental flexibility of the parts of the molecule. Such flexibility must be of critical importance in enabling the two antigen-binding sites which are formed by the N-terminal variable

Table 1 Physical, chemical and biological properties of the four human immunoglobulin G subclasses

Property	IgG1	IgG2	IgG3	IgG4
H chain type	γ_1	γ_2	γ_3	γ_4
Mol. wt	146 000	146 000	155 000	146 000
Hinge amino acid number	15	12	62	12
Number of interchain disulfide bonds	2	4	11	2
Plasma half-life (days)	21–23	20–23	7–8	21–23
Serum concentration (mg ml ⁻¹)	8	4	0.8	0.4

domains of the light and γ chains to engage bivalently with randomly spaced epitopes. Bivalent binding greatly enhances the functional affinity (avidity) of the antibody. The function of the hinge region, which is the site of most of the sequence differences between the γ chains of different subclasses is yet to be fully understood. Interest is focused on the variation in length of the hinge and its possible importance in spacing the efferent and afferent functional parts of the molecule.

The heavy chains are linked together at their mid-section, i.e. in the hinge region, by disulfide bonds and also through the pairing of the C γ 3 domains by strong noncovalent interactions. Each light chain is linked through its C-terminal cysteine to a heavy chain by a single disulfide bond and adheres also as a result of extensive noncovalent interaction through the pairing of the V_H and V_L domains, and of the C γ , and C_L domains. The strength of these noncovalent interactions is such that the polypeptide chains do not normally dissociate when the interchain bonds are broken unless denaturants are present.

The domains may be regarded as compact cylinders and the interdomain regions as short sections of

extended chain permitting a degree of flexibility in the interdomain regions, especially in the hinge region. The cylinders are resistant to proteases but proteolytic enzymes such as papain, trypsin and fibrinolysin can cleave IgG molecules at the hinge region, dividing the molecule into two basic functional units: a pair of fragments (Fab), which continue to express the antigen-binding function, and a single fragment (Fc) which readily crystallizes at low ionic strength and which interacts with complement (C1q) and continues to engage most of the effector functions of IgG. Pepsin cleaves C-terminal to the hinge disulfide leaving the two Fab fragments still disulfide linked as the F(ab')₂ bivalent antigen-binding fragment, but degrades the N-terminal domain of the Fc fragment leaving only the intact C-terminal domain, C γ 3, as the pFc' fragment. Fragments similar to the pFc' fragment (Fc') are also obtained from Fc by prolonged exposure to trypsin, papain and fibrinolysin. Specific proteolytic cleavage in the interdomain regions can be achieved by carefully controlled proteolysis of Fab or Fc following brief exposure to denaturing conditions such as low pH (~4.0). Fragments corresponding to individual intact

domains appear to retain their native conformation and continue to exhibit interdomain association as well as some of the biological properties associated with that domain.

The immunoglobulin fold

Each domain folds in a similar and characteristic way typical of all heavy and light chain domains as well as other polypeptides which form part of the immunoglobulin 'supergene' family. The polypeptide chain forms two layers of antiparallel β -pleated sheet to create a cylinder, one layer (X) consists of four β strands, the other (Y) of three. These layers form a hydrophobic envelope containing the intrachain disulfide bond which links them. The two cysteines that form this bond are conserved in almost all molecules that form the immunoglobulin fold. The β -strands are connected by loops which are evidently flexible, being rich in glycine residues. All constant region domains fold according to this basic structure.

The domains of the variable region have a slightly different structure in that there are two extra strands of β -pleated sheet associated with the three-strand (Y) face. This extension allows more scope for variety in the antigen-binding site. When the constant region domains pair, as in $C_L:C_{\gamma 1}$, $C_{\gamma 2}:C_{\gamma 2}$, $C_{\gamma 3}:C_{\gamma 3}$ the four-strand faces of the constant region domains face each other and, with the exception of $C_{\gamma 2}$, adhere on the basis of noncovalent interactions between conserved residues. The $C_{\gamma 2}$ domains are separated by a solvent channel lined on the X face with a carbohydrate moiety attached by *N*-glycosidic linkage through Asn297. The spatial relationship between the $C_{\gamma 2}$ domains is maintained by the hinge disulfide bonds and the interactions of the $C_{\gamma 3}$ domains. The biological significance of this feature is not understood, but loss of the disulfide or removal of the paired $C_{\gamma 3}$ domains disturbs this spatial relationship and may interfere with biological effector function. Additionally, the carbohydrate may play a biological role in securing this structure. Elimination or modification of the carbohydrate often has damaging consequences for the biological activity of IgG. Carbohydrate may also occur in the variable region if the acceptor sequence Asn-X-Ser/Thr occurs, that is in approximately 15% of V regions.

γ chain subclasses

Four subclasses are known in human ($\gamma 1$, $\gamma 2$, $\gamma 3$ and $\gamma 4$) and also in mouse IgG ($\gamma 1$, $\gamma 2a$, $\gamma 2b$ and $\gamma 3$) originally defined on the basis of specific antisera. There is little correspondence between the subclasses of the two species and it is thought that the subclasses evolved from a common ancestor indepen-

dently and subsequent to the divergence of the two species. While there are major differences in the biological properties of the subclasses in each species the sequence differences are small and confined mainly to the hinge region. The human subclass constant domains are approximately 95% identical but there are major structural differences in the hinge regions in terms of the number of disulfide bonds and the length of the region. The $\gamma 3$ hinge contains four tandem replications of the 15 residue segment (216–230) of the $\gamma 1$ hinge sequence. Electron micrographs reveal that this results in a considerably extended structure for the $\gamma 3$ protein. There are differences too in the point of attachment of the light chain disulfide bond to the heavy chain. In the IgG2, 3 and 4 subclasses the cysteine lies between the V_H domain and the $C_{\gamma 1}$ domain (residue 131) while in IgG1 the cysteine lies at the N-terminal end of the hinge (residue 220). The consequences of this are minimal since through the folding of the H chain these two points of attachment are close to one another.

Biological properties

Antigen binding is the primary function of the Fab region of IgG. The apposition of the three-strand faces of the V regions of the L and H chains leaves a cavity between them into which small molecules may fit, and the surface display of the hypervariable regions of the combined V regions forms a surface at the end of the Fab fragment which may bind in a noncovalent fashion to a protein or other macromolecular antigen over an area as large as $750 \text{ \AA}^2$. The $C_{\gamma 1}$ and C_L domains secure the interchain bonding between the H and L chains to provide a base for the antigen-binding V regions. The complement C4b fragment can bind to residues in the Fab heavy chain (Fd fragment) following activation of the classical complement pathway.

The Fc region is the locus for most of the other interactions of the molecule. Some of these have to do with the regulation of catabolism and excretion. The Fc fragment has a half-life in the circulation equivalent to that of the IgG from which it is derived. This is also true of the isolated intact (monomeric) $C_{\gamma 2}$ domain fragment of $\gamma 1$. Fab and $F(ab')_2$ fragments are rapidly excreted in the urine, usually unchanged. When desialylated, the carbohydrate on the Fc is recognized by the asialoglycoprotein receptor in the liver. Transfer across the placenta or by other means to the young is effected by a site in the Fc region. Binding to an Fc-specific receptor on the human placental syncytial trophoblast has been demonstrated with an affinity constant of the order of 10^7 M^{-1} . Subfragments of Fc are not able to bind to

this receptor, since the site extends over both Fc domains and requires an appropriate spatial relationship between the C γ 2 domains.

Complement activation by the classical pathway through C1q binding is effected through the C γ 2 domain. The intrinsic affinity for C1 is weak ($K_a = 10^4 \text{ M}^{-1}$). C1 activation takes place when multiple binding of the C1q occurs to several adjacently bound IgG molecules, thereby increasing the functional affinity to a value of the order of 10^8 M^{-1} . There is a marked difference in the ability of the subclasses of IgG to activate C1. The presence of glutamate at position 318 and lysine at both 320 and 322 has been shown to be essential for complement activation. This sequence, however, is present in all human IgG subclasses including those which activate complement only poorly (γ 2 and γ 4). Other residues are evidently important in the interaction or by facilitating it. Notable among the relatively few sequence differences is proline at position 331 (serine in γ 4). Replacement of these residues has been shown to affect the complement-activating activity of the modified immunoglobulin. Hypotheses based on differences in the hinge length or its relative flexibility appear now to have been disproven.

IgG binds to cell surface receptors on many types of cells to bring about an assortment of effects: the enabling of phagocytosis (monocytes, macrophages, neutrophils) or antibody-dependent cellular cytotoxicity (monocytes, macrophages and lymphocytes) or to effect feedback control on antibody synthesis (B and T lymphocytes). These properties vary among the IgG subclasses and in most cases the Fc fragments have the same property as the intact IgG, i.e. it does not appear to be modulated by the hinge or the Fab. The cellular Fc receptors have been classified into three categories according to their structure and affinity. All the sites on IgG which interact with these separate receptors appear to be located in the Fc region and, in the case of the Fc γ RI (which is the highest affinity receptor class), the site involves residues 233–237, at the N-terminal end of the C γ 2 domain close to the hinge region but coded in the C γ 2 exon. Site-directed mutagenesis experiments have indicated the specific requirement for a leucine residue at position 235 in Fc γ RI-binding molecules such as human IgG1, IgG3 and mouse IgG2a. Mouse IgG2b has glutamate in this position and does not bind Fc γ RI. The need for proline in position 331 has also been demonstrated. Fc γ RII binds to the same or a closely overlapping region since leucine 234 has been shown to be a necessary residue. It is postulated that Fc γ RIII may require sites on both Fc domains.

The implication that the FcR-binding region of IgG involves the near-hinge region of the molecule

presents conceptual problems for the topography of this interaction and runs counter to the simple view of the Fc receptor-bound antibody molecule sitting in the receptor on the cell surface like a letter Y sitting on its stem.

Binding of IgG also occurs to bacterial cell wall proteins such as protein A of *Staphylococcus aureus*. The site for this interaction has been shown by X-ray crystallography to involve residues in the inter-domain cleft between the C γ 2 and the C γ 3 domains, notably histidines 310 and 435. Histidine 435 is replaced by arginine in two allotypes of IgG3 and accounts for their not binding protein A. There is also evidence for secondary interaction between protein A and the Fab region of IgG.

IgM

Antibodies of the IgM class are the first immunoglobulins (Ig) appearing in the phylogeny and ontogeny of the immune system. Due to their predominance in large animals immunized with certain pathogenic bacteria for the purpose of generating protective antibodies, IgM were the first Ig separated to near absolute homogeneity. Although their concentration in the circulating blood is almost ten times lower (approximately 1.5 mg ml^{-1}) than that of the most represented Ig class, IgG, IgM play a major role in both the afferent and effector branches of the immune response. For instance, they serve as specific receptors for antigens on the surface of B lymphocytes, they constitute the major component of the primary antibody response to a specific antigen, and they efficiently activate the complement cascade, thereby enhancing opsonization of particulate antigens, such as bacteria and viruses.

Structure of IgM

IgM, previously known as γ -macroglobulin, exists as a variable size polymer of identical subunits. Each subunit (monomer) displays a molecular weight of 180 kDa and a sedimentation rate of 7.8 S. The IgM molecule possesses a double heterodimeric structure, consisting of two identical μ heavy (H) (μ_2) and two identical κ or λ light (L_2) chains. In healthy humans, the predominant polymer is the pentamer ($(\mu_2, L_2)_5$), with a molecular weight of 970 kDa and a sedimentation rate of approximately 19 S. The IgM pentamer contains one joining (J) chain of about 15 kDa molecular weight. The J chain is produced by the same B cell that makes the IgM. It contains at least six cysteins (Cys), but it does not share any amino acid sequence, nor does it display any antigenic cross-reactivity with any Ig H or L chains. Other human IgM polymers include the tetramer ($(\mu_2, L_2)_4$) and the hexamer ($(\mu_2, L_2)_6$), with the hexamer being the most frequent polymer after the pentamer. IgM are present as pentamers throughout the vertebrate evolutionary ladder, from the less evolved bony fishes (Osteichthyes) to mammals. Remarkable exceptions are most present-day bony fishes (Actinopterygii) and the amphibian *Xenopus laevis* which display IgM only as tetramers and hexamers, respectively. At the low end of the evolutionary ladder, cartilaginous fishes (Chondrichthyes) display IgM in the monomeric

form only. Monomeric IgM (μ_2, L_2) occur at a low concentration in the circulation of healthy humans, and are synthesized as such, rather than resulting from the degradation of polymers. Monomeric IgM are common in patients with Waldenström's macroglobulinemia, systemic lupus erythematosus, rheumatoid arthritis and ataxia telangiectasia. Many of these patients also display relatively high levels of circulating tetrameric and hexameric IgM.

Polymeric IgM can be split into (μ_2, L_2) monomers by mild reduction at neutral pH. Each of the two identical H chains of a monomer consists of five domains, i.e. one variable (V) and four constant, $C_{\mu}1$, $C_{\mu}2$, $C_{\mu}3$ and $C_{\mu}4$, H chain domains or regions, encoded by five different exons. The C_{μ} domains range in length from 105 ($C_{\mu}1$) to 111 ($C_{\mu}4$) amino acids (Figure 1). In contrast to IgG, IgA and IgD, IgM lacks a hinge region, which is substituted by a full $C_{\mu}2$ domain. The lack of a hinge region confers on IgM a more rigid structure than that of other Ig. Comparison of the IgM H chain primary structure to that of the other Ig classes entails the alignment of $C_{\mu}1$, $C_{\mu}3$ and $C_{\mu}4$ with the other Ig C_{H1} , C_{H2} and C_{H3} domains, except for IgE that also lacks a hinge region and possesses a four-domain C_{ϵ} H chain. Overall comparison of the amino acid sequence of human C_{μ} to that of the human $C_{\gamma}1$, $C_{\gamma}2$, $C_{\gamma}3$, $C_{\gamma}4$, $C_{\alpha}1$ and C_{ϵ} H chains yields identity values of 31, 31, 31, 34 and 28%, respectively. An extra 'tail' of 19 amino acids, including one Cys, is attached to the C-terminal end of the $C_{\mu}4$ domain (amino acid residue 557). This is not considered a domain and its primary structure is unrelated to that of any of the four C_{μ} domains (Figure 1). Studies of the mouse IgM have shown that the entire tail plus the amino acid at position 557, a glycine (Gly), are missing in the mature transcript of the membrane-anchored form of IgM (mIgM), and are substituted by a sequence of 41 amino acid residues that contains a highly hydrophobic (cell membrane anchoring) C-terminal stretch. Elements critical to the structure of the human IgM monomer are the Cys140 ($C_{\mu}1$) and the Cys337 ($C_{\mu}2$), which allow for the formation of the intrasubunit disulfide bonds to the L and H chain, respectively. Elements critical to IgM polymerization are the Cys414 ($C_{\mu}3$) and the Cys575 (tail). These Cys provide anchoring points

Figure 1 Human IgM subunit. V_H, V_κ and C_μ region domain boundaries, carbohydrate moieties, and complementarity determining regions are depicted. The C1q-binding site encompasses the C_μ3 domain only or the C_μ3 and part of the C_μ4 domains.

for the intersubunit disulfide bridges. Site-directed mutagenesis experiments involving serine (Ser) for Cys substitutions suggest that the availability of Cys575 in a Ser414 mutant monomeric molecule readily leads to assembly of a pentamer, that comprises one J chain bridging two subunits (dimer 'clasp'). Conversely, the availability of the Cys414 in a Ser575 mutant subunit readily leads to assembly of hexamers that do not include the J chain. The importance of the J chain for the assembly of the pentamer but not the hexamer is further emphasized by the observation that IgM hexamers readily assemble when monomeric subunits are allowed to spontaneously associate *in vitro* in the absence of the J chain. In the presence of the J chain, two predominant configurations of pentamers occur, in which Cys337-Cys337 is in series with both Cys414-Cys414 and Cys575-Cys575 (Figure 2). These configurations likely reflect the polymeric IgM structures most commonly occurring *in vivo*. Polymer IgM assembly can occur in the absence of the J chain and the Cys575, but it cannot be brought about by subunits lacking the 20 amino acid C_μ tail. Finally, IgM polymer assembly cannot rely merely on noncovalent subunit interaction, but requires disulfide bridging, as suggested in experiments involving Ser for Cys substitutions, by the ability of double Ser414, Ser575 mutants to generate IgM monomers, but the failure of these double mutants to generate polymers.

IgM, along with IgD and IgE, have a high carbo-

hydrate content of 10–12%. Carbohydrate groups are found in IgM H chains wherever the carbohydrate group acceptors are present, that is, one in C_μ1 (shared also by the corresponding domain in C_α1 and C_ε1), one in C_μ2, two in C_μ3 (one of which is also shared by the corresponding domain in C_γ1, C_δ and C_ε), and one in the tail (**Figure 1**). The carbohydrate group acceptor consists of the short sequence asparagine (Asn)-X-Ser/threonine (Thr), where X stands for any amino acid. It is suited for N-glycosidic linkages, in which N-acetylglucosamine attaches to the amino (-NH₂) group on the side chain of Asn. Both high mannose and 'complex' oligosaccharides with a molecular weight of 2500–3000 Da are present in IgM. 'Complex' oligosaccharides contain mannose, N-acetylglucosamine, galactose and sialic acid. The carbohydrate groups enhance the solubility of IgM in aqueous solution, and may stabilize their tertiary structure.

Initial electron microscopy examination of free IgM molecules revealed a typical planar 'star'-like shape for the pentameric form, with five pairs of Fab arms protruding from a central (Fc)₅ disc. More recently, it has been suggested that the planar axis of the F(ab')₂ arms may be at a right angle to the (Fc)₅ disc. After binding to a multivalent antigen on solid-phase matrix, e.g. flagella of *Salmonella*, a distortional conformation change takes place in the IgM polymer resulting in a dislocation of the central (Fc)₅ disc, possibly due to a rigidity of the F(ab')₂ arms

Figure 2 Structures of pentameric human IgM. (A) and (B) depict configurations of pentameric IgM based upon the two most likely disulfide bonding patterns. Other disulphide bonding patterns are possible, but are not considered for the purpose of this article. Open boxes depict V_H , V_L and C_μ domains. Black areas depict overlapping domains held together by noncovalent interactions. Full and half circles depict disulfide bonds and unpaired Cys residues, respectively. (A) depicts C_μ chains joined by homo pairs Cys414-Cys414 in parallel with Cys575-Cys575, and both in series with Cys337-Cys337; (B) depicts C_μ chains joined by homo pairs Cys337-Cys337 in series with both Cys414-Cys414 and Cys575-Cys575. In both (A) and (B), J chain is shown as bonded to Cys414 as well as to Cys575. (Courtesy of Ann C. Davis and Marc J. Shulman, modified from Davis and Shulman, 1989.)

which are not inherently altered. As a result, IgM engaged in antigen-binding takes the shape of a 'staple' or a 'multi-legged stool' with the $(Fc)_5$ disc on a plane different from that of the $F(ab')_2$ 'legs'.

IgM valency and complement activation

Reaction of pentameric IgM with haptens or small antigens results in the occupancy of all Fab antigen-binding sites, making IgM decavalent. Due to steric hindrance, reaction of IgM with larger ligands may result in occupancy of only five, or fewer, antigen-binding sites, suggesting that the valency of IgM is a function of the nature of the actual ligand. Owing to its high valency, the overall avidity of a whole IgM molecule for a given antigen, displaying repetitive epitopes, greatly exceeds the value of the intrinsic affinity of each Fab for the single epitope. Thus, the antigen size and nature have an important impact not only on the valency of an IgM molecule, but also on its binding strength. This is an important feature when one considers that naturally occurring proteinic and/or polysaccharidic antigens on bacteria, viruses and other microorganisms do often display repetitive epitopes.

The first step in the activation of the classical complement pathway is the binding of the C1q moiety of the latent C1 esterase to IgG or IgM. While at least two antigen-bound IgG are required for

complement fixation, a single IgM molecule can efficiently activate complement after binding Ag. In IgM, the C1q binding sites are located on the $C_{\mu}3$ and/or $C_{\mu}4$ domains (Figure 1). In its planar conformation, IgM bears a single C1q-binding site, allowing the binding of only one of the six globular heads present on each C1q molecule. This monovalent binding is characterized by a high dissociation constant (K_d), in the order of magnitude of 10^4 – 10^5 M^{-1} (low affinity). Dislocation of the IgM $(Fc)_5$ disc brought about by binding of the Fab arms to a multivalent particulate antigen leads to exposure of at least one more C1q-binding site on the $(Fc)_5$ disc. This allows multivalent binding of C1q, resulting in a 2–3 orders of magnitude increase in binding strength. Multivalent binding of C1q is enhanced in the IgM hexamer which activates complement up to 20-fold more efficiently than the canonical pentamer. Consistent with the notion that enhanced C1q binding by IgM results from a distortional process rather than an allosteric change, is the observation that antigen–IgM complexes efficiently activate C1 when prepared in antibody, but not antigen, excess. Thus, the engagement of IgM in a lattice is an absolute prerequisite for complement fixation by IgM following the binding of soluble antigens. It is conceivable that such an engagement entails a distortion of the Fab arms that results in a better exposure of the $(Fc)_5$ disc, in a fashion similar to that following the bind-

ing of IgM to particulate antigens. Activation of the C1 esterase by IgM leads to the assembly of the C3-convertase, C4b2a, and subsequent deposition of C3b, and its inactivated forms, iC3b and C3d, on the antibody molecules engaged in the lattice. C3b, iC3b and C3d can greatly enhance the engulfment of antigen by readily mediating attachment of the antigen-IgM complexes to the complement receptors CR1, CR3, and CR2 or CR4, respectively, that are present on the surface of different blood cells, including erythrocytes, granulocytes, monocytes, macrophages, natural killer (NK) cells, B lymphocytes and T lymphocytes.

IgM in the antigen-induced antibody response

Monomeric membrane (m)IgM, along with mIgD, constitute the receptors for antigen on all virgin B cells. mIgM⁺ lymphocytes, whether mIgD⁺ or mIgD⁻, make up the whole B cell repertoire in neonates and in axenic animals, and account for the majority of the B cell repertoire clonotypes in adults. Cross-linking by antigen of mIgM and mIgD on virgin IgM⁺IgD⁺ B cells triggers the mechanisms that lead to lymphocyte activation, proliferation, and, eventually, substitution of mIgM by mIgG, mIgA or mIgE in differentiated antibody-producing B cells and memory B cells. It has been speculated that the rigidity of IgM (due to the lack of a hinge region) plays a major role in signal transduction into the B cell. Polyclonal recruitment of surface IgM⁺IgD⁺ B cells during the early phases of a primary antibody response results in production of IgM antibodies displaying, in general, a low to moderate affinity for antigen. These IgM constitute the bulk of a primary response, and are encoded, in general, by unmutated V(D)J gene segments. They are heterogeneous in their degree of polymerization with a relatively high representation of the hexameric form. In contrast to these early IgM, the IgM of the 'late' primary response can display a significant level of somatic point-mutations. Selection of some of these mutations by antigen can occur prior to Ig class switching. Full-blown antibody somatic diversification and selection, however, and the resulting increase in antibody affinity are associated, in general, only with IgG, IgA or IgE class-switched B clonotypes. Ig class switching is dependent on T cell help that includes engagement of CD40 on the surface of B cells by CD40L on T cells. A defective CD40L molecule, as occurring in patients with inherited mutations, does not allow for effective CD40 engagement and Ig switching, and it is associa-

ted with absolute lack of IgG, IgA or IgE, and compensatory levels of IgM, 'hyper-IgM syndrome'.

IgM as natural antibodies

Most of the IgM antibodies that are produced in the early stages of an antigen-induced primary response or as a result of an antigen-nonspecific polyclonal B cell activation, e.g. by Epstein-Barr virus in humans or bacterial lipopolysaccharides (LPS) in mice, display the functional features of the Ig that are referred to as 'natural antibodies or autoantibodies'. Natural antibodies bind a variety of microorganisms, including viruses, bacteria, protozoa, metazoa parasites and fungi, as well as heterologous plasma and tissue components. The presence in the normal sera of a population of molecules reactive with a broad array of different antigenic determinants and displaying physicochemical properties similar to those of the antibodies that appear, usually at much higher titer, following immunization has been recognized for almost a century. The terms 'natural antibodies' or 'spontaneously produced antibodies' had been used to distinguish these Ig from the antibodies that have been elicited by intentional or known immunization. The vast majority of the natural antibodies are IgM. Their spectrum of reactivity is not limited to foreign antigens, but also includes self antigens, such as hormones, e.g. insulin or thyroglobulin, cell constituents, e.g. DNA, myosin, actin, tubulin, glycoproteins or phospholipids, and antibodies, particularly, the Fc fragment of autologous IgG (rheumatoid factor, RF). Most natural IgM antibodies are polyreactive, i.e. they bind, in a dose-saturable fashion, two or more antigens, even very different in nature, such as proteins, polysaccharides and nucleic acids, in general with low to moderate affinity (K_d , 10^5 – 10^7 M⁻¹). In most polyreactive IgM, the binding to a given antigen can be efficiently cross-inhibited by another antigen, suggesting that structures responsible for binding different antigens vastly overlap. Experiments involving shuffling of H and L chain complementarity-determining regions (CDR) and framework regions (FR) of human natural antibodies suggest that the somatically generated H chain CDR3 provides the main structural correlate for binding multiple antigens.

Most polyreactive IgM are produced by a discrete subset of the B cell repertoire expressing, at low intensity the surface CD5 marker (B-1 cells). B-1 cells account for a significant proportion of the normal human B cell repertoire. They constitute the vast majority of B lymphocytes in the late stages of fetal development and in the newborn. Expression by B-1 cells of unmutated polyreactive IgM would provide

the structural correlate for the high degree of 'connectivity', i.e. interclonal idiotypic cross-reactivity, characteristic of the fetal and neonatal B cell repertoires. As a consequence, B-1 cells and natural IgM antibodies may play a major role in shaping the overall diversity and specificities of the developing, and, eventually, the adult, B cell repertoire. These cellular elements and IgM antibodies play a major role in the first line of defense against invading microorganisms, as well as in blood group incompatibility, and in hyperacute rejection of xenografts. Their importance in the defense against infections is further suggested by their high degree of representation in primordial phylogenetic stages: polyreactive IgM are the only antibodies found in sharks and torpedo fish. Owing to their polymeric nature and multivalency, polyreactive IgM efficiently aggregate bacteria and viruses, mediate complement-dependent lysis, promote and enhance opsonization and phagocytosis. The high levels of circulating IgM binding to the IgG Fc fragment and other self antigens found in patients with bacterial, viral and parasitic infections suggest that most pathogens do readily activate B-1 cells to secrete polyreactive antibodies. Not only do these IgM directly bind antigens on invading microorganisms, but they also amplify, through their effective RF activity, the biological activity of specific IgG aggregated on the surface of bacteria, viruses or parasites. Antigen-aggregated IgG, present in the circulation from the beginning of a secondary response, would, in turn, efficiently boost RF production. In contrast to the RF IgM appearing early in the primary response, some of the RF IgM arising during the secondary response possess a much higher affinity for the IgG Fc fragment, as exemplified by the ability of RF IgM arising in rats during the specific response to *Trypanosoma lewisi* to terminate the *T. lewisi* infection when transferred into animals displaying only trace amounts of circulating specific IgG.

IgM, autoimmunity and neoplasia

Owing to their broad antiself antigen reactivity, natural IgM antibodies could provide the templates for affinity matured class-switched autoantibodies, and B-1 cells can, under certain circumstances, play a role in the establishment of autoimmune phenomena. B-1 cells are greatly increased in a number in patients with rheumatoid arthritis and Sjögren's syndrome. In rheumatoid arthritis patients, these cells spontaneously proliferate and secrete large amounts of IgM with RF activity. Some of these IgM RF are polyreactive, display a low affinity for the IgG Fc fragment, and are encoded by unmutated V genes. Others are monoreactive, display a higher affinity for

IgG Fc fragment (K_d , 10^{-7} M $^{-1}$), and are encoded by extensively mutated V genes. The inherent proliferative potential of IgM-producing B-1 cells and their stimulation by antigen may be synergistic and may contribute to premalignant or malignant B lymphoid transformation. A relatively high incidence of B lymphoid malignancies occurs in patients with Sjögren's syndrome and rheumatoid arthritis. Further evidence pointing to a link between IgM-producing B-1 cells, autoimmunity and malignant transformation stems from the features of the monoclonal antibodies associated with a variety of human B cell neoplasms, including chronic lymphocytic leukemia (CLL), small lymphocytic lymphoma, Waldenström's macroglobulinemia and other paraproteinemias. The vast majority of CLL B cells are B-1 and produce, in general, IgM. Like monoclonal Waldenström's IgM paraproteins, many of these monoclonal IgM possess RF and other antiself antigen reactivities. Other autoantibodies of the IgM class that are characteristically associated with malignant B cell neoplasia or benign monoclonal gammopathy are cold agglutinins that react with various polysaccharidic red cell determinants. Transient cold agglutinins of the same IgM class and similar antigen-reactivity occur commonly in patients with infections, particularly those by *Mycoplasma pneumoniae* or by Epstein-Barr virus (infectious mononucleosis). Thus, the neoplastic transformation of natural IgM antibody-producing B clones is associated with fidelity of the function defining the physiological B cell clonotypic progenitor.

I-J

Thomas J Rogers, Department of Microbiology and Immunology,
Temple University Medical School, Philadelphia, USA

The background to this controversial molecule lies in studies reported in the 1970s by both Murphy and Tada and their colleagues, suggesting that suppressor T cells bear determinants which mapped to a novel locus of the I region of the murine major histocompatibility complex (H-2 complex). This site was termed the Ia-4 locus, and this locus was found to mark a new I-region gene which was termed I-J. Through the use of certain recombinant mouse strains, the I-J gene locus was found to map to a region between what are now referred to as the I-A and I-E loci of the H-2 complex. The recombinant mouse strains utilized for the mapping of the I-J locus included the B10.A(5R)[I-J^k], B10.A(3R)[I-J^b], B10.A(9R)[I-J^k] and B10.HTT[I-J^s] strains. The recombination points of the B10.A(5R) and B10.A(9R) strains define the centromeric (left) boundary, and the recombination points of the B10.A(3R) and B10.HTT strains define the right boundary of the I-J locus. It has been assumed that B10.A(3R) are congenic with respect to the I-J locus with B10.A(5R) mice, and the same is true of the B10.A(9R) and B10.HTT strains.

alleles have been generated successfully. A number of monoclonal antibodies against I-J have been generated as well. It has been the experience of numerous investigators that these antibodies react with antigen-specific suppressor T cells. Many of these cells are capable of secreting factors which are themselves suppressive. The I-J-specific antibodies also appear to react with an epitope present as a part of certain of these suppressor cell factors. The relationship of the membrane and secreted forms of the I-J-bearing molecules remains unclear.

The actual function of the I-J molecule is uncertain but may be related to the interaction of the individual suppressor cell populations. It has been found, in certain cases, that the functional activity of suppressor cells (and suppressor factors) is restricted at the I-J locus. This is additional evidence of the significance of the I-J gene product in the function of these regulatory cells. In addition, this suggests the possibility that the target cell population for the I-J-bearing suppressor factor must bear an I-J allele-specific binding structure for the factor.

Relationship of I-J to suppressor T cells

By utilizing a number of recombinant mouse strains, anti-I-J alloantisera which recognize many of the I-J

Cellular source of the I-J molecule

The initial studies which defined the I-J locus showed rather convincing evidence that I-J is produced by

suppressor but not helper T cells. More recent studies have shown that I-J is not expressed in B cells. On the other hand, a subpopulation of helper cells, and some (but not all) helper T cell clones, appear to express the I-J molecule. It has been proposed that the I-J gene product expressed on T helper cells may represent an alternative 'form' of the I-J molecule, as certain monoclonal I-J-specific antibodies react only with suppressor or helper T cell I-J epitopes. Other monoclonal I-J-specific antibodies appear to react with both 'forms'.

Evidence has been reported by certain laboratories suggesting that I-J may be produced by macrophages. The nature of the expression of I-J on accessory cells remains unsettled. There is some evidence to suggest that macrophages bear a binding structure for I-J-positive suppressor factors. Anti-idiotypic antisera (generated in response to monoclonal I-J-specific antibodies) react in an I-J haplotype-specific manner with accessory cells. It has been suggested that the I-J restriction in the interaction between suppressor cell populations actually represents an I-J restriction between the suppressor cell factor and an accessory cell.

Biochemical characteristics of the I-J molecule

The actual I-J structure has not been identified with any certainty. However, the suppressor factors which are recognized by polyclonal and monoclonal I-J-specific antibodies are protein in nature. The I-J-bearing polypeptide may be found either alone or linked (by a disulfide bridge) to a second (non-I-J-bearing) polypeptide. The two-chain factors are usually composed of an I-J-bearing chain linked to an antigen-binding chain. The I-J-bearing chain appears in most cases to be a polypeptide of 25–30 kDa. The antigen-binding chain may represent some part of the T cell receptor α chain.

The I-J structure expressed on the surface of both helper and suppressor T cells has also been examined. Using NP-40 lysates and immunoprecipitation with I-J-specific antibodies, the I-J molecule is detected as an 81–90 kDa dimer composed of 42–46 kDa glycoprotein subunits. In these studies, the I-J dimer was found to be distinct from the T cell receptor α/β heterodimer.

Molecular biology of the I-J gene

The region of the H-2 complex which spans the interval between I-A and I-E from the congenic strains B10.A(3R) and B10.A(5R) has been cloned and sequenced. This interval is less than 3.4 kb, a size that may be too small to encode for a polypep-

tide larger than 20 kDa. Moreover, T cells which express the I-J determinant do not appear to transcribe this region. These cells do not possess a rearrangement in the I-A or I-E genes either. Clearly, the structural gene for I-J must be elsewhere.

In view of these results, it is difficult to explain the genetic mapping initially reported for the I-J locus. It has been suggested that I-E or I-A genes contribute to the expression of the I-J gene product. Both I-A and I-E transcripts are undetectable in T cells which express I-J determinants. However, studies with both I-E chimeric and I-E $_{\alpha}$ transgenic mice show convincing evidence that suggests that the I-E locus contributes to the I-J phenotype. This notion is consistent with related evidence that shows that I-E has a significant impact on the T cell receptor V $_{\beta}$ allele repertoire in various mouse strains.

Conclusions

The I-J locus and gene product remain matters of great controversy at this time. Much of the skepticism concerning I-J will be alleviated once the I-J gene(s) has been cloned. More recent studies have suggested that the I-J determinant is associated with a 13 kDa protein termed the glycosylation-inhibiting factor. The glycosylation-inhibiting factor isolated from suppressor cells is recognized by I-J-specific antibodies and possesses suppressive activity. Additional questions remain, however, regarding the basis for the genetic restriction in the function of this factor, and the apparent haplotype-specificity in the recognition by I-J-specific antibodies.

IMMUNE ADHERENCE

Figure 1 Immune adherence of *Streptococcus pneumoniae* to human erythrocytes. Dark ground illumination. (Photograph courtesy Dr RA Nelson.)

The term immune adherence (I-A) was first used by RA Nelson to describe a phenomenon that had already been known for 50 years and had been referred to as the red-cell adhesion test. I-A is part of one of the most important biological activities of the complement system, being involved in the phagocytosis of complement-coated particles by cells of the neutrophil and mononuclear phagocyte system. Nelson described the adherence of particulate antigens such as bacteria to human and other primate erythrocytes (Figure 1) or rodent platelets (Figure 2) in the presence of antibody and complement. It is

Figure 2 Immune adherence of sheep erythrocytes to guinea pig platelets. (Photograph courtesy Dr RA Nelson.)

now known that adherence is through the CR1 receptor through C3b, iC3b, and C4b. Complement activation in I-A may be through the classical or alternate pathway. Thus, I-A of zymosan by the alternate pathway of complement can occur in the absence of antibody. I-A to erythrocytes and platelets is part of a wider phenomenon including immune adherence to the CR1 receptor also present on neutrophils and macrophages. I-A to red cells and platelets is also involved in the clearance of complement-coated particles by neutrophils and cells of the reticuloendothelial system, acting as a means of presentation of antigenic particles or immune complexes to phagocytic cells in these tissues.

Originally described with bacteria and protozoa, I-A also involves the surface of helminths and viruses, as well as soluble antigens such as ovalbumin. It has been used as a diagnostic test in the clinical laboratory, particularly in syphilis serology, where the TPI-A (*Treponema pallidum* I-A) test has had varying popularity. I-A serology may be used by observing the adherence of particulate antigens such as bacteria to the red-cell surface under the microscope or by observing the hemagglutination patterns at the bottom of the wells of a titration dish (Figure 3). An I-A hemagglutination assay has been applied to the study of herpes simplex and varicella-virus infections, and also used for the quantitative estimation of infantile gastroenteritis antigens in the stools.

Other uses of I-A have been to demonstrate activation of C3 on the surface of macrophages which have ingested asbestos *in vivo*, detected by I-A of human, but not sheep, red cells. Moreover, in studying the complement reactivity of soluble immune complexes, I-A has been a useful marker of the ability of the complexes to activate C3 and to bind to the CR1 receptor. The I-A phenomenon has been used to demonstrate the CR1 receptor sites in solid tissues, using the adherence of EAC (erythrocyte antibody complement) complexes to tissue sections. The demonstration of CR1 sites in glomeruli using this technique has suggested an alternative arrangement for immune complex deposition in the kidney. The use of EAC complexes to quantitate B cells in the blood or exudates is also an example of the I-A phenomenon, as B cells are known carriers of the CR1 receptor.

IMMUNE COMPLEXES

Urs E Nydegger, Central Laboratory of Haematology, Inselspital/University Hospital, Berne, Switzerland

Binding between antigen and antigen-specific antibody results in a reaction product which is an antigen–antibody complex or simply ‘immune complex’. Immune complexes interact with many cells of the immune system, causing activation or inactivation, and they might trigger the cytokine network. In the presence of plasma proteins, especially those belonging to the complement system, immune complexes will grow to more than strictly complexes between antigen and antibody. In fact, a number of different proteins have been identified as becoming fixed to immune complexes, thereby building up large protein constructions of which antigen and antibody are only a portion. The proteins found on immune complexes include the complement proteins C1q, C4b, C3b and factor H as well as anti-antibodies (rheumatoid factors, anti-idiotypes) and fibronectin. Both exogenous (foreign) and endogenous (self, autologous) antigens may trigger immune responses that result in the formation of immune complexes.

Immune complexes are three-dimensional structures forming a lattice-type of sequence between antigens and antibodies with a ratio that may vary essentially according to the size of the antigen, the density of antigenic epitopes, and the isotype, subclass, poly/monoclonality and affinity of the antibody. The interaction between antigen and antibody does not result from chemical bonding but rather is due to electrostatic forces. Therefore, the physicochemical properties of a given immune complex preparation is the result of a dynamic process between build-up and breakdown, contributing to constant variability of the characteristics of immune complexes *in vivo*. The immune complex structure is favoured by the Y-shaped configuration of the immunoglobulin molecules and by their abundance of water-repelling nonpolar groups known to favor autoaggregation of immunoglobulin M (IgM) or IgG in solution.

Detecting immune complexes in bodily fluids and tissues

Detection of immune complexes in clinical samples is of interest in a number of human and animal diseases. Furthermore, in countless test systems, immune complexes are the *in vitro* reaction product of laboratory diagnostic tests for detection of either specific antibodies or antigens. For demonstration of *in vivo* formed immune complexes in serum or other body fluids, where the antigen involved is unknown, two approaches may be pursued: 1) quantitative estimation of immune complexes with characterization of the complexed immunoglobulin isotype and bound complement component using conventional screening tests; 2) analysis of the antibody specificity and possibly of complexed antigen using more elaborate technology (Figures 1 and 2).

Rapid screening tests for the detection of immune complexes in a large number of samples are mostly based on the ability of immune complexes to interact with naturally occurring humoral and cell receptors. A classical technique is the C1q-binding assay that is based on the ability of immune complexes to interact with the globular head domains of the first component of human complement, C1q: purified, radiolabeled C1q binds to the immune complexes

Figure 1 Isolation of immune complexes from the remainder of serum proteins. The figure depicts a possible protocol starting with coprecipitation of macromolecular proteins using 2–3% polyethylene glycol which precipitates proteins larger than approx 300 kDa. The precipitate is enriched in immune complexes but is still contaminated with other macromolecular proteins. In order to remove the latter proteins, the precipitate is passed over solid phase staphylococcal protein A which retains immune complexes; after thorough washing, the complexes are eluted from the column with glycine buffer.

Figure 2 Analysis of immune complex composition and specificity. The purified immune complexes are now ready for further analysis, e.g. for separation and examination of antigen and/or antibody. An easier procedure for purifying immune complexes is by cryoprecipitation but only a few immune complexes (e.g. a portion of complexes with hepatitis C infection) have the property of precipitating in the cold.

and the resulting C1q-immune complex assemblage is detected using size exclusion with polyethylene glycol (PEG). An even simpler technique mixes serum with low concentrations of PEG known to precipitate oversized macromolecules with subsequent analysis of the pellet. Monoclonal antibodies to C1q insolubilized on microtiter plates may be used to capture C1q in the analytical sample already bound to immune complexes *in vivo*, with subsequent demonstration of immunoglobulins in the captured material. Other solid-phase immune complex detection assays are possible using conglutinin (K) or rheumatoid factors as capture for immune complex bound complement. It is said that K preferentially binds small complexes and those having a high antigen:antibody ratio. On the other hand, C1q-binding assays identify immune complexes with a lower antigen:antibody ratio and a greater size range. In addition, K binds complexes that contain the small residual degradation fragment of C3, C3d, whereas C1q only binds those activating complement by the classical pathway of complement activation.

For detection of immune complexes in more elaborate assays, cellular receptors may be used, such as the Fc receptor (FcR) present on macrophages or platelets and, in the most successful of this type of assay, the Raji cell test, iC3b receptors (complement receptor CR3) present on *in vitro* transformed lymphoblastoid cell lines. The erythrocyte-antibody-complement (EAC) rosette inhibition test measures

the inhibition by immune complexes of rosette formation between a subpopulation of peripheral B lymphocytes and sensitized sheep erythrocytes carrying C3. The sensitivity of these techniques is generally good and is in the microgram per milliliter range, but the disadvantage is that cell preparations must be used, which makes them tedious and cumbersome for routine use. Standardization is difficult, but a fair comparison of results among different laboratories is noted with use of international reference preparations. Similar technology using cellular receptors may provide insights into the immune complex constituent that actually ligates to cell surface receptors. By blocking specific types of cell surface receptors with monoclonal antibodies, Fc binding can be distinguished from F(ab')₂ binding or binding via immune complex fixed C3b and/or C4b.

The availability of preparative techniques providing a partially purified material allows further immunochemical and biochemical characterization of the complexes. Several techniques make the study of molecular composition of immune complexes for clinical research possible: direct electron microscopic examination of precipitates obtained by polyethylene glycol or cold precipitation; dissociation of complexes at acid pH (Figures 1 and 2), by urea or heat; *in vitro* manipulation of complexes by adding suspected antigen, with a possible shift of the antigen: antibody ratio towards antigen excess so that loss of their complement fixing ability can be ascertained; and absorption of immune complexes on concanavalin-coated polystyrene beads allowing their further purification and study. Using this type of technology, it is possible to obtain information on the composition of immune complexes in disease (Table 1).

Physiology of immune complex formation and experimental immune complex disease

Study of antibody-antigen interactions can now be modeled at the atomic level. For example, with viral peptide epitopes, the epitope may bind in a shallow crevice on the Fab surface with, sometimes, only portions of the epitope deeply penetrating into the Fab (Figure 3). Numerous hydrogen bonds, salt bridges and electrostatic forces now come into action to hold together what we designate an immune complex.

Under physiological conditions, the transient formation of immune complexes is normal and will remain undetected by usual methods because their concentration does not reach the sensitivity of the detection techniques. The physiological relevance of immune complex formation may be summarized as follows.

1. Through their binding to antigen, antibodies present antigen to the removal systems of the body, by a phenomenon called opsonization, which leads to elimination and destruction of the antigen. Monocytes, macrophages and granulocytes, as part of the reticuloendothelial system in liver, spleen, bone marrow and skin, function as immune complex-retaining filters, their performance possibly deciding whether antigen removal is successful or turns into chronic inflammatory disease.
2. Antibodies will carry antigen to the lymphoid tissues and keep it fixed there on the surface of follicular dendritic cells, which allows optimal immune responses following prolonged antigen recognition by specific lymphocytes.

Upon injection of preformed complexes of known composition into animals, large complement-fixing immune complexes immediately bind to circulating cells bearing the CR1 receptor (CD35) for C3b.

Table 1 Selected examples of established immune complex diseases

<i>Nosological entity</i>	<i>Involved antigen</i>
<i>Serum sickness, iatrogenic</i>	Animal antitoxins, antisera, drugs, antilymphocyte globulin, HgCl ₂ , gold, D-penicillamine
<i>Infectious agents</i>	
Glomerulonephritis of infected atrioventricular shunts	<i>Staphylococcus epidermidis</i>
Glomerulonephritis of malaria	<i>Plasmodium malariae</i>
Glomerulonephritis of schistosomiasis	<i>Schistosoma mansoni</i>
Immune complex disease of hepatitis B infection	Hepatitis B virus
Cryoglobulinemia/vasculitis of hepatitis C infection	Hepatitis C virus
<i>Autologous antigens</i>	
Systemic lupus erythematosus (SLE)	DNA, nucleoproteins
Rheumatoid arthritis	IgG as an antigen for rheumatoid factors
Mixed cryoglobulinemia	IgG as antigen (for anti-idiotypic antibodies?)
Glomerulonephritis	Renal tubular antigens
Goodpasture's syndrome	Glomerular basement membrane
Thyroiditis with thyroid carcinoma	Thyroglobulin

Figure 3 Complex between a viral peptide epitope of poliovirus and a neutralizing antibody Fab (as displayed by computer modeling). The structural and chemical complementarity between antigen and antibody shows clearly, and negative charges in the antigen binding pocket evidently contribute to binding. (Reproduced with permission from Wien et al (1995).)

These cells are erythrocytes in human and nonhuman primates and platelets in various rodents and subprimates – including mice, guinea pigs and rabbits. Studies in primates have shown that circulating erythrocytes rapidly interact with exogenously infused or *in vivo* formed immune complexes and carry them to the hepatic and splenic reticuloendothelial system, where the complexes are stripped from the erythrocytes and further processed by the mononuclear phagocytes. Decomplementation of the animals, thereby preventing association of C3b to immune complexes, makes immune complex fixation to erythrocytes impossible, facilitating diffuse deposition of immune complexes outside the reticuloendothelial tissues. CR1 in humans is found not only on erythrocytes, from which it was isolated in the late 1970s by Fearon, but also on neutrophils, monocytes and lymphocytes. The presence of such receptors on lymphocytes provides an immunoregulatory function of immune complexes; their fixation to lymphoid tissues permitting prolonged immune recognition of the antigen and, perhaps, the maintenance of immunological memory.

The interaction of immune complexes with complement leads to ionic fixation of the globular domains of C1q to the C γ 2 domain of IgG, or the C μ 3 domain of IgM after these antibodies have formed immune complexes. The IgG- and IgM-binding site on the C1q globular domains is strongly electrostatic. The IgG residues involved in the binding to C1q are charged residues, Glu318, Lys320 and Lys322. Subsequent C4b and C3b binding further contribute to coating of immune complexes by

complement. In the circulation at any one time, the proportion of immune complexes bound to erythrocytes is dependent not only on the rate of binding but also on inactivation of CR1-bound C3b, which leads to release of the immune complexes from the erythrocyte surface. The released complexes remain coated with iC3b and C3dg and are incapable of activating complement any further but maintain a capacity to cause an inflammatory response. The enzyme responsible for C3b inactivation is factor I: its concentration and activity determine release reactions and hence influence the kinetics of the exchange of immune complexes between erythrocytes and plasma.

It is at the level of the reticuloendothelial system – mainly in liver and spleen – that immune complexes become discharged from the erythrocytes in transit through the circulation. The iC3b- or C3dg-bearing immune complexes remain in the reticuloendothelial system, where they interact with iC3b receptors (CR3, CD11b) or C3dg receptors (CR4, CD11c) that are expressed on phagocytic cells. Failure of the erythrocyte shuttle transport system or dysfunction of the different processing steps of immune complexes in the reticuloendothelial system may lead to a chronic persistence of complexes in the circulation, thereby predisposing to their entrapment in kidney, skin, lungs, retina and other organs.

The complement system thus emerges as the major immune complex-processing protein system that confers upon a variety of circulating and tissue fixed cells the potential to dispose of these complexes. Human erythrocytes are now known to autonomously inhibit the complement-mediated solubilization of immune complexes bound to their surface, suggesting that these cells would control some physicochemical properties of the complexes they carry.

At the beginning of the twentieth century, Arthus described a clinical syndrome that developed after the injection of horse serum into rabbits, and Clemens von Pirquet recognized that antigens not only induce antibodies but are also responsible for serum sickness. Immune complexes were identified as the toxic products responsible for tissue injury of individuals with serum sickness. We now know that, for the Arthus reaction to occur, relatively large amounts of immune complexes have to be localized in the vessel walls and in perivascular areas. Both passively adsorbed and locally formed immune complexes will react with complement and induce release of anaphylatoxins, such as C3a and C5a, and cytokines, which enhance vascular permeability and generate other chemotactic factors, attracting polymorphonuclear leukocytes to the site of the lesion. An increase in

vascular permeability evidently favors the leakage of circulating immune complexes into the extravascular compartment. *In vitro* studies further suggest that the binding of immune complexes to tissue components may cause direct, complement- and inflammatory cell-independent tissue injury by stimulating oxygen radical release.

At this stage, inflammation becomes largely dependent on interaction of immune complexes with the Fc receptor apparatus. In fact, FcR signaling on such cell types as macrophages, neutrophils and natural killer (NK) cells recruits cellular tyrosine kinases, followed by elevation of intracellular calcium and release of inflammatory leukotrienes, prostaglandins and hydrolases and the transcription of genes encoding for cytokines.

Immune complexes containing IgG suppress interferon γ (IFN γ)-induced activation of the Fc γ RI gene by preventing tyrosine phosphorylation, a finding that explains the impairment of tumoricidal activity and enhancement of major histocompatibility complex (MHC) class II expression in macrophages by immune complexes. A considerable diversity of cellular responses to immune complexes thus emerges, which is largely due to actions at different types of FcR. In turn, FcRs are themselves under control of various cytokines. Thus, a network of regulatory factors exists which can become disturbed by immune complexes. Furthermore, immune complexes are now known to induce and stimulate interleukin 10 (IL-10) production from macrophages, thereby inhibiting antimicrobial responses (e.g. against *Listeria monocytogenes*). In turn, immune complexes induced IL-10 production when experimentally used to provoke acute alveolitis, an activity that is favorable for the host, because IL-10 decreases tumor necrosis factor α (TNF α) production, thereby attenuating injury. IL-10 thus downregulates not only inflammation directed at foreign invaders but also at self constituents (Figure 4).

Since the original definition of serum sickness, a great variety of diseases have been found to resemble the immune complex model described in rabbits. Particularly well studied are the autoimmune hemolytic disease and chronic membranous glomerulonephritis in New Zealand black mice. Further immune complex-type diseases in animals involve viral antigens such as Aleutian disease of mink, lymphocytic choriomeningitis, in which immune complex-induced lesions develop, and lactic dehydrogenase-elevating virus (LDV) infection in mice, with the production of often lifelong levels of circulating immune complexes.

Augmented production of immune complexes, and/or their reduced removal, plays a crucial role in

Figure 4 Intervention of immune complexes with opposing sets of cytokines. Immune complex-induced increased production of IL-4 and IL-10, and immune complex-induced suppression of IFN γ . IL-10 suppresses IFN γ -production by helper T lymphocytes and NK cells. In addition, IL-10 suppresses the production of several proinflammatory, macrophage (M ϕ)-derived cytokines, including TNF α , IL-1 α , IL-1 β , IL-6, IL-8, granulocyte-macrophage and granulocyte colony-stimulating factors. IL-10 also inhibits expression of MHC class II antigen on monocytes and upregulates inducible nitric oxide synthase in macrophages. Exogenously administered IL-10 has been shown to protect rats from lung injury after intrapulmonary deposition of IgG immune complexes. CTL, cytotoxic T lymphocyte.

the pathogenesis of many immune complex-related diseases in humans, as illustrated by systemic lupus erythematosus (SLE), rheumatoid arthritis (RA) and HIV infection. **Table 1** lists a number of nosological entities in which immune complexes play a relevant immunopathological role and in which their therapeutic removal may improve the patient's condition.

Because complement is so important to immune complex processing, adverse consequences with regard to humoral immune defense are understandable in hypocomplementemic patients. In patients with inherited complement deficiencies, increased serum concentrations of immune complexes are found associated with deficiencies of components of the classical pathway of complement activation C1, C4 and C2. In acquired complement deficiency, however, low levels of these and other components (C3, C5, C5b-9) may be a result of chronic complement activation either by the inflammatory process or directly by immune complexes. This is mostly reflected by the demonstration of low levels of C3, C4 and other components and high levels of the complement component breakdown products C3dg, C3a and C5a. In many patients, the levels of circulating immune complexes and those of complement breakdown products correlate significantly.

Clinical aspects in human medicine

Immune complexes are found in the circulation and/or other biological fluids of patients with a large spectrum of diseases not resembling each other, such as autoimmune, infectious and neoplastic disorders. This proves that elimination of antigens in the stage of immune complexes is a common feature to many diseases, and symptoms may not necessarily result from their presence. In fact, in many circumstances, it is not possible to differentiate between a role for immune complexes in physiological antigen removal and a deleterious pathogenic factor. In glomerulonephritis the pathogenic role of immune complexes is generally accepted. The following immune complex diseases are frequently associated with nephritis: SLE, polyarteritis, cryoglobulinemia and many microbial diseases such as bacterial endocarditis, leprosy, malaria, trypanosomiasis, hepatitis B and C infection and dengue hemorrhagic fever. In contrast, RA, polymyositis, dermatomyositis, cutaneous vasculitis, fibrosing alveolitis and the acquired immune deficiency syndrome (AIDS) typically do not involve the kidneys. The antigens that have been identified in immune complex-mediated glomerular disease include endogenous antigens (nuclear, brush border, thyroglobulin, immunoglobulin, carcinoembryonic and other tumor antigens) and exogenous antigens (bacterial, viral, parasitic, fungal) and others such as drugs and toxic agents. In RA, levels of immune complexes roughly correspond to clinical severity and/or progression of the disease. In SLE, no constant correlation between levels of circulating immune complexes and disease activity and kidney or skin involvement is found. In addition, a range of drugs may interfere with immune complex-complement interaction; examples here are hydralazine, isoniazide and penicillamine, which all inhibit covalent binding of C4 to complement-activating surfaces, such as provided for by immune complexes. Chronic circulation of immune complexes over prolonged time may reflect insufficient management of infectious attacks in certain bacterial and viral diseases, for example infective endocarditis or hepatitis B virus infection. Very high concentrations of immune complexes are seen in AIDS and hepatitis C cryoglobulinemia. They have been related to the occurrence of complications found in patients exposed to HIV and hepatitis C, such as vasculitis and thrombocytopenia.

At this point it should be noted that the quality of antimicrobial antibodies is crucial in determining the host's capacity to eliminate immune complexes; thus, antibodies may bind to viruses without necessarily mediating their neutralization and/or removal. Such a binding may even be deleterious, as it may facilitate entry of viruses into cells richly endowed with FcR through FcR-dependent mechanisms – one example being the colonization of macrophages by HIV.

IMMUNE RESPONSE

Anthony Quinn, Claudia Raja-Gabaglia, Susanne C. Schneider, Todd Braciak and Eli E Sercarz, Department of Microbiology and Molecular Genetics, University of California, Los Angeles, USA

The immune response involves a coordinated set of interactions among host cells and the protective molecules they produce upon encountering a pathogen or antigen, the purpose of which is to prevent dangerous incursions and then to restore homeostasis. The immune system must not only confront external, invasive challenge from microorganisms but also the possibility of internal attack from tumor cells, and occasionally autoaggressive attack from its own defensive forces (autoimmunity). The required complexity of this response is illustrated by the fact that throughout evolution, viruses, bacteria and other parasites have accommodated to the host response by developing their own unique strategies designed to circumvent the host defense system. Likewise, appropriate responses in the host have evolved to cover these contingencies, with some accompanying redundancy. Thus, there appear to be many nodal points throughout the system where a choice of reactive pathways is available. Indeed, the host immune response consists of two interacting systems, one innate and one adaptive.

Innate system versus adaptive system

When it is realized that some microbial populations can double in 20 minutes under ideal circumstances, it is evident that the specific immune system can only protect effectively in the case of aggressors for which it has previously developed memory. Therefore, the innate immune response has developed into a system of a generic sort, always in place, capable of immediate responsiveness to foreign encroachment. It is the consequence of long-term evolution which has its origins in the invertebrate phyla and includes mechanisms of phagocytosis, chemotaxis, cellular mobilization, pattern recognition and coordinated action. The mammalian innate system comprises various features, including protective plasma proteins, phagocytic cells (granulocytes) and physical barriers.

One interesting feature is the way in which aspects of innate and adaptive systems interact. Let us consider two such important cellular components of the innate system: the dendritic cells (DCs) and the natural killer (NK) cells. The dendritic cells perform a guarding function, by which they are stationed at all outposts of the body – in the skin, where they are

called Langerhans cells, or in various organs such as the lungs, liver and kidneys, where they bind and ingest foreign or intrinsic invaders. Entry of an infectious agent induces an inflammatory response, largely carried out by other members of the innate system, which leads to activation of DCs. This enables the DC to carry antigen, which it has taken up and processed, to the peripheral lymphoid organs where it is presented to specific T and B lymphocytes to start the specific immune response.

The NK cells also play a dual role and provide molecules known as cytokines to modulate the activities of other cell types. NK cells can be effector cells, killing virus-infected or transformed cells, and like the DCs, are vital intermediaries with the adaptive immune system.

The principal effector cells of the adaptive system are T and B lymphocytes. Unlike the innate system, the adaptive system develops in response to antigenic challenge. The specificity of this system requires the evolution of antigen receptors with the capacity to recognize millions of distinct molecular structures; however, each antigen specificity is represented by only a limited number of lymphocytes. Therefore, two key features of this system are the enormous expansion of specific lymphocytes following antigen exposure and the storage of specific memory in 'memory cells', which upon subsequent challenge are able to respond rapidly. Most importantly, the system is a migratory one, in which responsiveness occurs in defined locations. Evolution has finely tuned the homing mechanism for lymphocytes and antigen-presenting cells (APCs) so that their meeting will lead to productive interactions.

In the rest of this entry, we describe the intricate and interactive maneuvers of subspecialized groups of cells involved in the defensive function.

Elements of the adaptive defense system

The humoral and the cell-mediated immune responses are the two major components of the acquired immune response. Its components are principally the B lymphocytes (B cells) and the T lymphocytes (T cells), and their interaction is required for a successful response. These lymphocytes express highly specific antigen receptors on their surface in a

clonally restricted manner such that each lymphocyte bears fine specificity for a given structural motif. The antigen-specific receptor present on the surface of B cells is the immunoglobulin (Ig) molecule in its membrane-bound form. When a B cell encounters an antigen that interacts with its surface immunoglobulin, provided it receives the necessary T cell signals, it proliferates and differentiates through several generations into immunoglobulin-secreting plasma cells and memory cells. Antigen-specific immunoglobulins or antibodies detected in the serum or other bodily fluids are indicative of antigenic encounter and an immune response. Monomeric antibody molecules, comprising two identical heavy chains (α , δ , γ , ϵ or μ) and two identical light chains (κ or λ), can be described functionally as having a 'Y' shape. Sequences in the arm are highly variable among molecules and form two identical antigen-binding sites. The stem of the 'Y', or constant region, contains more conserved sequences and endows the five distinct antibody classes (IgA, IgD, IgG, IgE and IgM) with functional properties. During an immune response, the first class of antigen-specific antibody detected in the serum is the pentameric IgM molecule, but a switch then occurs to IgG, IgA or IgE. In T cell-dependent antibody responses, switching is accomplished in conjunction with T cell and cytokine signaling.

The functions of the humoral or antibody response include neutralization of a pathogen and/or its toxic products by antibody binding, to prevent infection or toxic damage, respectively. Additionally, antibody can act as an 'opsonin' to facilitate the phagocytosis of pathogens by macrophages, which in turn present parts of the microbe to specific lymphocytes. A third function is activation of the complement cascade. Complement is a group of plasma proteins that bind to antigen-antibody complexes, enhancing opsonization or, in some cases, directly killing the bacterium or the infected cell.

T cells also respond to stimulation of their unique antigen receptors (T cell receptor, TCR) by proliferating, differentiating and secreting cytokines. The majority of T cells express a TCR composed of an α and a β chain, while a minority of cells express a heterodimer of γ and δ chains. Unlike B cells, T cells cannot recognize native antigens but require short peptides derived from them to be displayed on the surface of an APC in association with molecules of the major histocompatibility complex (MHC). Dendritic cells, macrophages and activated B cells are professional APCs which capture antigen by endocytosis, then digest or process the antigen so that it can be placed within a binding groove in MHC class II molecules for presentation to T helper cells

(T_H) carrying the CD4 coreceptor which contacts an invariant region of the class II molecule.

The other type of MHC molecule, the class I, is present on all nucleated cells and binds peptides from endogenous self proteins and intracellular pathogens, such as viruses and some bacteria. Destruction of such pathogens is accomplished through killing the host cell by cytotoxic T lymphocytes (CTLs). Cytotoxic T cells that recognize peptides in association with MHC class I molecules bear the CD8 molecule on their surface, which acts as a coreceptor and contacts an invariant region of the class I molecule.

TH_1 versus TH_2 : the importance of an appropriate response

Antigen-specific activation of T cells results in the clonal expansion of specific lymphocytes and the secretion of cytokines. The T cells can be classified into two major subsets according to their pattern of cytokine secretion: type 1 and type 2 T cells. T helper type 1 cells (Th_1) secrete interferon γ ($IFN\gamma$), interleukin 2 (IL-2) and tumor necrosis factor β ($TNFB$), while the type 2 T helper cells (Th_2) secrete IL-4, IL-5, IL-6 and IL-10, among others. Differentiation down the Th_1 pathway is regulated by the monocyte-derived cytokine IL-12, while Th_2 development is governed by IL-4. Most importantly, the Th_1 and Th_2 pathways are mutually antagonistic, so that progression in one direction tends to be persistent. The pattern of $CD8^+$ T cell cytokine secretion is not as clear but there appears to be a similar polarization.

Type I cytokines help to control viral infections by activating NK cells and CTLs. The type II cytokines, especially IL-4 and IL-5, are relevant to immune responses to extracellular parasites and the development of allergies by virtue of their ability to induce IgE production in B cells and enhance the growth of mast cells. The disease leishmaniasis illustrates the importance of activating the appropriate T helper subset. Protection from the disease is dependent upon the activation of the Th_1 pathway which leads to $IFN\gamma$ production, macrophage activation and parasite killing, and inhibits IL-4 production. In experimental mice, deviation towards a Th_2 response can result in death. Multiple factors can influence T cell function and cytokine polarization, including the genetic background of the host, the type of APC, the nature of the costimulatory and accessory molecules, the affinity of the antigen for the MHC and the antigen-MHC complex for the TCR.

Antigenic determinants (dominance versus crypticity)

The processing of antigens into peptides capable of stimulating T cells, when associated with MHC molecules, is a vital part of the immune response. The specific immune response to an antigen is directed to only a limited number of all possible peptides that can theoretically be generated from this protein, the so-called 'immunodominant determinants'. This phenomenon has been studied classically using the lymph node proliferation assay. 'Dominant' determinants are capable of inducing *in vitro* proliferation of lymphocytes ('recall') that have been primed *in vivo* with the whole protein. When 'dominant' determinants are used to immunize, they can raise a response which can be recalled by the whole protein antigen. 'Cryptic' determinants are only capable of inducing a response when in the peptide form, and this response is not recalled by the whole protein. A large repertoire of T cells directed against self remains available for reactivity, as only dominant determinants induce thymic tolerance.

Activation versus tolerance

While antigen recognition is an essential feature in immune activation, it also is critical for the development of immunological self tolerance in the host. According to the two-signal model of T cell activation, TCR ligation by peptide-MHC complexes provides a primary signal that has to be complemented by a second signal for a naive T cell to become fully activated. Costimulatory molecules and their receptors, such as B7 and CD28, respectively, provide this second signal, while other pairs of accessory molecules function to stabilize the interaction between the two cells. Shortly after T cell activation, expression of an additional B7 interacting molecule, CTLA-4, may be induced, which can downregulate further T cell immune expansion.

The interaction between the accessory molecule CD40 on B cells and CD40 ligand (CD40L, gp39) on T cells also functions as a costimulatory signal for both the T cell and the B cell. Ligation of the TCR by a peptide-MHC complex on an APC such as a B cell leads to the upregulation of CD40L expression on T cells, which mediates a signal via CD40 on the B cell, leading subsequently to increased expression of B7 molecules. The enhanced expression of B7 on the B cell allows full activation of the T cell through CD28, which then secretes cytokines that induce the differentiation of the B cell. Thus, CD40 plays a role in the regulation of both humoral and cell-mediated immune responses.

While orchestrating its defenses, the immune system must also take steps to prevent cellular damage which accrues via friendly fire (autoimmunity). In contrast to activation, which leads to the stimulation and expansion of certain lymphocytic clones, immunological self tolerance is achieved by the selective elimination from its armament of the lymphocytes which are reactive with dominant determinants on self antigens. At least three mechanisms have been described for the induction of tolerance: clonal deletion, clonal anergy and active suppression via cytokines or regulatory lymphocytes which recognize certain immunoglobulin or TCR molecules. Clonal deletion is accomplished in part during the establishment of central tolerance, where high-affinity, autoreactive T and B cells are physically removed during thymic and bone marrow selection, respectively, via antigen-induced apoptosis. However, negative selection in the primary lymphoid organs alone is not sufficient for the maintenance of self tolerance as many potential target antigens are not expressed in the thymus and bone marrow and others are developmentally regulated and appear after the repertoire has been established. Autoreactive T cells which escape the thymus are rendered 'unresponsive' when they are stimulated in the periphery by nonprofessional APCs which lack costimulatory molecules (naive B cells and parenchymal cells). In fact, successful T cell clonal expansion requires the presence of activated B cells, which in turn are dependent upon T cell help. Thus, the discrimination between activation and tolerance induction is the product of several factors, including the nature of the APC and the local environment.

Hyper- and hyporesponsiveness: examples of dysfunctional immune responses

Clearly, T cells bearing TCRs capable of recognizing self antigen-MHC complexes are present in healthy individuals, yet autoimmune disease does not normally occur. However, if a self reactive T cell population becomes activated, a vigorous inflammatory response can be created, spreading to other previously cryptic determinants on the self antigen ('intramolecular spreading'). In the absence of regulation, such an incident may perpetuate into a chronic, autoimmune condition. Conversely, the recognition of a self determinant can be beneficial, as when a TCR peptide on an autoimmune effector T cell is targeted by a regulatory T cell.

On the other hand, immunodeficiency brings equally serious problems as hyper-responsiveness. The devastation induced by the human immunodeficiency virus (HIV) is a stark example of this.

ciency virus (HIV) in targeting CD4-bearing cells of the immune system is well known. When the loss of CD4 cells becomes acute, most immune responsiveness fails, as these cells are crucial for the induction of other activities in the system. One additional example of an inadequate immune response may be the outgrowth of malignant tumors in otherwise healthy individuals. Many experimentally induced tumors are quite immunogenic, e.g. immunization with a small or attenuated tumor dose protects from further challenges with the same tumor, indicating that the immune system is capable of recognizing and killing the tumor cells. Unfortunately, this is not the case for most spontaneous tumors which are non-immunogenic (hence their spontaneous appearance). They are, however, antigenic – capable of inducing a specific immune response if appropriate costimulatory signals are provided. Nonimmunogenic tumors transfected with mixtures of cytokines (e.g. IFN γ) and/or with costimulatory molecules (B7) can attain the capacity to induce an immune response: they are efficiently rejected and subsequent long-term protection against the parental tumor becomes established ('memory'). Another way to efficiently prime the immune system to specific tumor antigens is to present them via a professional APC, such as a DC. Both approaches have been effective in inducing a protective immune response to a subsequent challenge with the same tumor, when combined with cytokine administration.

The previous sections describe how the immune system constantly accumulates information to fine tune the type of response that adequately meets the challenge. Although we and others have used a military analogy to describe the system, it can also be viewed as expending continuing effort throughout life 'to know itself', and to maintain the organism's self integrity.

IMMUNE RESPONSE (Ir) GENES

Jerold G Woodward, Department of Microbiology and Immunology, University of Kentucky Medical Center, Kentucky, USA

Immune response (Ir) genes can be defined as any gene locus at which different alleles affect the magnitude of an immune response. Thus, Ir genes were identified on the basis of a complex phenotype and, not surprisingly, comprise a heterogeneous group of structural genes. Nevertheless, genes encoded within the major histocompatibility complex (MHC) clearly have the most dramatic effect on the immune response to a variety of antigens, and thus became the first well-characterized Ir genes.

Historical background

From the beginning of this century, immunologists had noted that there were differences in the ability

of individual animals to mount an immune response to an antigen, and that these differences were heritable. Because the animals used in early experiments were outbred, and the antigens generally complex proteins or whole organisms, the genetic influence was complex and involved a large number of genes. In an attempt to simplify the complexity of antigens, immunologists turned to the use of synthetic amino acid copolymers (two or more amino acids linked in linear or branched chains). In 1963, the laboratories of Maurer and of Benacerraf reported that the immune response of guinea pigs (both antibody production and delayed-type hypersensitivity (DTH)) to synthetic copolymers such as poly-(Glu,Lys), or poly-L-Lysine was under genetic control, and that the

response segregated as a single autosomal dominant gene. McDevitt and Sela also demonstrated that the immune response of mice to branched-chain copolymers such as (T,G)-A-L was under single gene control and designated this the immune response 1 or Ir-1 gene. Using inbred mouse strains, they subsequently mapped the Ir-1 gene to the H2 complex, in a region termed the I-region. Very shortly thereafter, a number of antigens were shown to be under Ir gene control. While these genes all mapped in the H2 complex, intra-MHC recombinant mice revealed the existence of multiple loci. The Ir-1 locus was soon renamed Ir-1A. A distinct locus, Ir-1B, was defined by the antibody response to IgG2 allotypes. Ir-1C was defined by its ability to complement with Ir-1A in the response to the synthetic copolymer GLT.

Independently, the groups of David, Frelinger and Shreffler, and Hauptfeld and Klein, identified lymphocyte cell surface antigens that mapped within the I-region of the H2 complex. These antigens were designated class II MHC molecules (the class I antigens were first identified by Peter Gorer in the late 1930s) and because they mapped within the I-region, they were referred to as immune-associated, or Ia antigens. Shortly thereafter, the phenomenon of MHC restriction was discovered by Doherty and Zinkernagel, and it became apparent that both class I and class II MHC molecules were 'restriction elements' in the recognition of antigen by T cells.

As more and more evidence accumulated that the Ir genes originally identified were identical with Ia antigens, and that class I molecules could also manifest Ir gene effects, a generally accepted model emerged. Ir gene effects (at least those mapping within the H2 complex) could be explained as the consequence of MHC restriction and variability of different polymorphic alleles of class I and class II MHC antigens to 'present' antigen to T cells. Finally, in the last 10 years, we have developed a detailed understanding of the mechanism of MHC restriction and can explain in considerable detail, the molecular mechanism of MHC-linked Ir gene effects.

MHC-linked Ir genes

The original Ir genes defined by the response to synthetic copolymers are, in fact, the structural genes for the Ia antigens, referred to as class II MHC genes. The Ia antigens in the mouse consist of two similar cell surface glycoproteins, I-A and I-E, each of which is composed of an α and a β chain. The four genes encoding these molecules are A α , A β , E α and E β . The genes are highly polymorphic (except for E α) and exist in multiple allelic forms. They are also

codominantly expressed such that, generally, both alleles at each locus are expressed in a heterozygous individual. In heterozygous individuals, codominant expression also allows for the pairing of an α polypeptide chain encoded on one chromosome with a β polypeptide chain encoded on the other chromosome, forming a 'hybrid' Ia molecule that is not found in either parent. The existence of hybrid Ia molecules explains the complementation of Ir genes observed by several investigators. Additional β chain genes exist, and some appear capable of coding for protein, however protein products have not been identified, and their role in MHC restriction and Ir gene control remain unknown.

The three-dimensional structure of MHC class I and class II molecules has been solved by X-ray crystallography. Both of these structures reveal a cleft formed by two α helices, and it is clear that peptide fragments of antigen occupy these clefts. In order for antigen to be recognized by the T cell, it must first be degraded and presented as a peptide bound in the groove of an MHC molecule. The T cell receptor then recognizes the antigen, as well as a portion of the MHC molecule. The specificity for interaction of the T cell receptor with a particular MHC molecule is determined during T cell development in the thymus by a process called positive selection. This dual specificity of the T cell receptor for peptide and a specific allele of MHC antigen is called MHC restriction. The MHC restriction specificities of the T cells are dictated by the MHC antigens expressed in the thymus during T cell development. Thus for a T cell to recognize and respond to antigen, two criteria must be fulfilled: the proper antigenic peptide must be bound in the groove of an MHC molecule on an appropriate antigen-presenting cell (APC), and the MHC molecule to which the antigen is bound must be the proper restriction element for that T cell. Finally, the T cell repertoire is influenced by negative selection in the thymus, where T cells reactive to self antigen plus self MHC are clonally deleted. The result of this type of selection is that there can be 'holes' in the T cell repertoire that vary, depending on the expression of MHC and polymorphic self antigens in different individuals.

The mechanisms described above led to the development of two general models to explain Ir gene control of the immune response. One model, referred to as the determinant selection model, states that different polymorphic variants of Ia molecules differ in their capacity to bind and present particular peptide antigens. Therefore, non- or low-responsiveness would be due to the relative inability of certain MHC molecules to bind a particular antigen peptide. The alternative, although not mutually exclusive, expla-

nation is that the low response phenotype is due to a lack of specific T cells for that particular antigen, the so-called 'hole in the repertoire' model. Since the T cell repertoire is, to a large extent, dictated by the polymorphic MHC alleles expressed in the thymus during ontogeny, this phenotype would also be controlled by the MHC class I and class II antigens. There is now strong experimental evidence indicating that both models are correct. The ability of MHC molecules to discriminate between different peptides was demonstrated by peptide-binding studies using solubilized MHC molecules and labeled peptides of known MHC restriction. Thus, the peptide fragment HEL 46-61 of the hen egg lysozyme molecule is the immunodominant peptide in I-A^k-positive mice, and is presented by the I-A^k molecule. The I-A^d molecule does not present this peptide and mice with this allele are nonresponders to this peptide. *In vitro* binding assays revealed that peptide HEL₄₆₋₆₁ binds to the I-A^k but not the I-A^d molecule, suggesting that the nonresponsiveness of I-A^d mice is due to the inability of the I-A^d molecule to bind and present this antigen to T cells. The binding of HEL₄₆₋₆₁ can be inhibited by competition with some unlabeled peptides but not others. There is a direct correlation with the ability to compete for binding and the ability to be recognized by the relevant T cell. Thus, if a peptide cannot bind, it cannot stimulate a T cell, establishing that Ir gene control does operate at the level of peptide binding. However, not all peptides that bind are capable of stimulating T cells. For example, the autologous mouse lysozyme sequence binds quite well to the I-A^d molecule, but does not stimulate mouse T cells, presumably due to self-tolerance.

The finding that autologous lysozyme peptides bind to I-A^d molecules suggests that peptide binding to MHC molecules is not the sole factor in determining immune responsiveness. There are now many examples of peptides that bind to particular I-A or I-E molecules, but do not stimulate T cells. For example, the lambda repressor protein, cl₁₂₋₂₆, binds equally well to I-A^d and I-E^k, but only stimulates T cells when associated with I-A^d. Since the peptide is capable of being recognized by the T cell, and does bind to I-E^k, these results indicate that the nonresponsiveness to cl₁₂₋₂₆ in association with I-E^k is due to a lack of cl₁₂₋₂₆-specific T cells restricted to this MHC class II molecule.

The class I molecules are also capable of functioning as Ir gene products in a manner analogous to the class II molecules. There is, however, a qualitative difference due to the T cell subsets (CD8⁺ cells as opposed to CD4⁺) that respond to class I plus antigen, and the types of antigens that become associated with the class I molecule on the cell surface. In gen-

eral, class I molecules preferentially associate with endogenously synthesized antigens, while class II molecules associate with exogenously added antigens. Nevertheless, clear Ir gene effects are associated with class I molecules. Analogous to the results with class II antigens, Townsend and colleagues demonstrated that endogenously synthesized viral gene products are processed and become associated with class I MHC molecules as peptide fragments. They further demonstrated that peptide binding is selective and usually depends on the appropriate responder class I allele. As with the class II molecules, peptide binding to class I antigens is required for immune responsiveness, however, not all peptide-class I combinations will stimulate T cells, presumably due to a lack of specific T cells in those instances.

We can now explain the basis for MHC-controlled, Ir gene phenomena. The first requirement for an immune response to antigen is that a peptide fragment be bound to a particular MHC molecule. If a peptide cannot bind to a particular MHC molecule, then there will be no response to that particular peptide-MHC combination, and that allele will be a nonresponder allele for that particular peptide. On the other hand, it is possible for a peptide to bind perfectly well to a particular MHC molecule, but not elicit a response due to a hole in the T cell repertoire. Since the T cell repertoire is primarily controlled by the MHC molecules expressed in the thymus during T cell ontogeny, this Ir gene effect also maps to the MHC structural genes.

In spite of these restrictions on the immune response, most individuals respond quite well to a variety of antigens. In mice of I-E⁻ haplotypes, like C57BL/6, only one class II molecule, the I-A^b molecule, is available for presentation of antigens, and yet these strains are fully immunocompetent. The reasons for this are several-fold. First, peptide binding to any given MHC molecule is extremely nonspecific, so that a wide variety of different peptides are accommodated. Second, since most antigens are complex proteins, there will usually be some peptides from any given protein that are capable of binding to a particular MHC molecule. Thus, Ir gene effects are most apparent when the number of antigenic determinants is limited, as in the case of synthetic copolymers, or proteins that differ from the responding species by a very few number of amino acids.

Non-MHC-linked Ir genes

A number of non-MHC-linked genes have also been shown to affect the magnitude of the immune response to particular antigens, and therefore fulfill

the requirements for Ir genes. However, unlike the MHC genes, the mechanisms of action are poorly understood. The Ir-2 locus controls the antibody response to the blood group antigen Ea-1. Ir-2 appears to be a single locus, mapping to chromosome 2 of the mouse, for which nonresponse is dominant. The Ir-3 locus controls the response to the Pro-Lys backbone of the synthetic copolymer (Phe,G)-Pro-L. This antigen is also under MHC-linked Ir gene control, making Ir-3 difficult to study. The Ir-4 locus controls the antibody response to the H2.2 specificity of the H2D^b molecules. The Ir-5 locus controls the antibody response to the mouse Thy-1 antigen and maps approximately 17 cM telomerically from H2. As with Ir-3, Ir-5 interacts with H2 in the response. The Ir-7 locus controls the response to the cell wall polysaccharide of group A streptococci. Three alleles have been described that interact in a complex fashion.

Genetic analysis of Ir phenotypes indicates that there are many additional loci that can manifest Ir gene effects. In fact, any polymorphic self protein, in theory, can influence the immune response to foreign antigen through the process of negative selection in the thymus. This is most dramatically seen in the case of the endogenous retroviral superantigens. Although not strictly a self molecule, these integrated defective retroviruses show mendelian inheritance and produce protein products that are indistinguishable from other self proteins. Mouse mammary tumor virus 7 (MMTV-7), previously known as Mls-1^a, produces a superantigen that interacts with all T cells bearing V_β 6, 7, 8.1 and 9 T cell receptors. Consequently, mice carrying MMTV-7 clonally delete most, if not all T cells bearing these particular V_β T cell receptors (TCR), resulting in a large 'hole' in the T cell repertoire. Finally, the genes encoding the immunoglobulin and T cell receptor V regions are technically Ir genes since the presence of particular V genes varies between haplotypes. Many haplotypes have large deletions of TCR or Ig V genes, significantly altering the T or B cell repertoire in these mice.

Human Ir genes

A number of studies have demonstrated HLA associations with the immune response to different antigens. While it is more difficult to formally demonstrate Ir genes in humans, it is clear that the human MHC gene products function in an analogous manner to the mouse. One example where Ir gene effects in humans most likely play a role is the association of HLA alleles with autoimmune diseases such as

ankylosing spondylitis associated with HLA-B27, and rheumatoid arthritis and juvenile onset diabetes associated with HLA-DR4. The HLA association is with susceptibility, not resistance, suggesting that the associated HLA antigens may be Ir genes controlling the response to some unknown antigen, either foreign, or self.

Perhaps the most striking and relevant example of Ir gene effects in humans is the demonstration by Hill and colleagues that the HLA-B*5301 allele controls the binding of a particular peptide from the liver stage-specific antigen of the malarial parasite, *Plasmodium falciparum*, thus making B*5301 an immune response gene for this peptide antigen. Most importantly, this peptide represents a critical cytotoxic T lymphocyte epitope and the B*5301 allele (which is present at greatly increased frequencies in West African populations) confers a high degree of resistance to malaria. Thus, immune response genes in the form of MHC polymorphisms can indeed play a pivotal role in the response to complex antigens such as the malarial parasite, and appear to be capable of evolving due to the influence of natural selection by the pathogen.

IMMUNE RESPONSE IN VITRO

Immune responses *in vitro* and *in vivo* are closely related and interdependent, their components being effectively the same. Formulating *in vitro* methodologies is dependent on the level of understanding of immune responses *in vivo*, while insight into the *in vivo* environment can be assisted by *in vitro* experimentation. As *in vitro* studies have progressed, further clarification of leukocyte interactions has been forthcoming, giving us the *in vitro* immune response systems employed today. These methodologies have found a number of applications. One of the more recent is the analysis of vaccine efficacy, allowing the differentiation of vaccinated from non-vaccinated animals. A more widely applied use is in hybridoma technology: *in vitro* immune responses have been used to produce the antigen-specific lymphoblasts required for hybridoma generation. An area which has seen considerable application of immune responses *in vitro* is fundamental immunological research. It is now possible to analyze, in a detail not otherwise possible, how different cell populations communicate and interact with each other, and the means by which lymphocytes recognize and react with antigen, to name just two widely studied examples. The following sections look in more detail at the methodologies employed, and how variations therein have been applied to particular analyses.

The basis of the immune response *in vitro*

Immune responses *in vitro* can be effected as either primary or secondary responses. The former make use of leukocytes from naive (nonimmunized) animals, the latter from animals previously immunized with the antigen in question. Both types of response require the same basic components of lymphocytes, monocytes and intercellular communications, including cytokine activity (Table 1).

Cellular requirements

As with responses *in vivo*, B lymphocytes react directly with the antigen for which they are specific, but complete differentiation into antibody-producing plasma cells requires immunological help from helper T (T_H) lymphocytes (Figure 1). A few antigens can stimulate B lymphocytes independently of T_H lymphocytes, but the majority of antigens are T_H

lymphocyte dependent. Antigen-stimulated precursor cytotoxic T (T_C) lymphocytes also require immunological help from T_H lymphocytes (Figure 1). In contrast to the B lymphocyte, both T_H and T_C lymphocytes require antigen to be processed and presented in peptide form associated with major histocompatibility complex (MHC) molecules on the surface of antigen-presenting cells (Figures 1 and 2). When the peptide is associated with MHC class II, T_H lymphocytes can be stimulated; when associated with MHC class I, T_C lymphocytes can be stimulated (Figure 2). Monocytes, the related dendritic cells and, to a lesser degree, macrophages appear to be the main antigen-presenting cells. B lymphocytes can also present antigen, but apparently only to memory T lymphocytes; the monocytic antigen-presenting cells present to both naive and memory T lymphocytes. Accessory cells, such as endothelial cells and fibroblasts, play important additional roles in intercellular signaling (Figure 3), and are important for maintaining viability in a culture.

Cytokine requirements

The cytokines of the *in vitro* immune response are linked to the T_H lymphocytes and monocytes which produce them (Figure 1). Table 2 shows examples of those which have been most extensively studied and applied to *in vitro* immune responses. Whether exogenous cytokines are to be applied, or only the stimulation of the cytokine-producing cells within a culture, will depend on the type of *in vitro* immune response under study, and the objectives of the experiment. Nonetheless, it is the cognate interactions between helper cells and effector cells, or their precursors, which are essential for optimum immune responses *in vitro*.

Antigenic requirements

Antigen requirements *in vitro* will not necessarily relate to those *in vivo*, and are normally determined by experimentation. Immunogenicity *in vivo* is not a guarantee that an *in vitro* response can be stimulated. Generally, the more complex an antigen – in terms of structure and topography – the more efficient will be the induction of an immune response (see below under the topics of initiation of primary and secondary immune responses *in vitro*).

Table 1 The basic requirements for *in vitro* immune responses

Component	Conventional sources	Use
Monocytic APC	Lymphoid organs, blood	Antigen presentation; intercellular signaling; endogenous cytokine production
Dendritic cell APC	Lymphoid organs, blood, skin	Antigen presentation; intercellular signaling
B lymphocytes	Lymphoid organs, blood	Antigen-specific antibody production; antigen presentation to memory T _H lymphocytes (secondary immune responses)
T lymphocytes	Lymphoid organs, blood	Antigen-specific immunological help (T _H lymphocytes, via their cytokine production); endogenous cytokine production (T _H lymphocytes); antigen-specific cytotoxicity (T _C lymphocytes)
Endothelial cells	Lymphoid organs, tissues/organs containing microvascular capillaries	Intercellular signaling; endogenous cytokine production
Fibroblast accessory cells	Lymphoid organs, lung, skin	Intercellular signaling; endogenous cytokine production
Cytokines	Recombinant biotechnology, mitogen-activated mononuclear cell cultures	Lymphocyte proliferation and differentiation; antigen processing (activity depends on the cytokine or mixture of cytokines)
Antigen	As required for the study	Stimulation of the lymphocyte proliferation, either directly (for B lymphocytes) or indirectly after processing and presentation by APC (for T lymphocytes)

APC, antigen-presenting cell.

Establishment of the immune response *in vitro*: practical considerations

Sources of cells for immune responses *in vitro*

Mononuclear cells (lymphocytes and monocytes) from secondary lymphoid organs (lymph nodes, spleen or tonsils), as well as peripheral blood have been successfully applied to *in vitro* cultures (Figure 4; Table 1). For lymphoid organ cell preparations, mild enzymatic treatments of collagenase plus DNAase are preferred (Figure 4); preparation of blood cells is by centrifugation through density gradients of Ficoll-Diatrizoate (e.g. Ficoll-Hypaque) (Figure 4). Accessory endothelial cells can be obtained from lymph nodes and microvascular areas (such as umbilical cord, skin and lung tissue), while fibroblast cultures can be prepared from lungs and skin (Table 1), again using collagenase digestion or trypsinization (Figure 5).

In vitro deviations from *in vivo*

The cellular component of an *in vitro* immune response (Table 1) must contain viable and potentially active leukocytes. Problems with respect to this essential requirement can arise due to differences between the *in vitro* and *in vivo* immune response systems. Within secondary lymphoid organs, in which immune responses are initiated, there is a high cell concentration and a cellular network permitting

efficient interaction. These are essential for the maintenance of the cells in a viable and responsive state. When the cells are removed for *in vitro* culture, both the network of interactions is broken and the cell concentration reduced. Although preparatory procedures for *in vitro* culture may result in cell damage, modern methods render this minimal and of minor consequence compared to the reduced intercellular communication and signaling *in vitro*.

The problem of cell death *in vitro*

The loss of the *in vivo* intercellular interactions abrogates the delivery of signals required to control programmed cell death (also referred to under the morphologic term of apoptosis). This is particularly the case with T and B lymphocytes, but not with monocytic cells, endothelial cells or fibroblasts, which can be cultured without much problem. The majority of T and B lymphocytes may enter programmed cell death within the first 3 days of culture, in the absence of stimulation and cosignaling. Stimulation of the lymphocytes *in vitro* with antigen can prevent programmed cell death, providing that the correct cosignaling is also present (Figures 1 and 3, Table 1). Accessory cells can be employed to this end. However, their presence in conventional preparations of cells for *in vitro* immune responses is often inadequate, due to the reduced cell concentration employed with *in vitro* cultures. Consequently,

Figure 1 The principal components required for the immune response *in vitro*. T_H lymphocytes and antigen-presenting cells (APCs), which are usually the monocytic or dendritic cell APCs, are essential for all immune responses. The T_C lymphocytes will be studied in the context of antigen-specific cytotoxicity, while the B lymphocytes will be of interest for analyses of antigen-specific antibody production. Although the T_H lymphocytes and APCs produce cytokines, it may also be necessary to supplement certain cultures with exogenous cytokines, particularly at the initiation of the response. Accessory cells, such as endothelial cells and fibroblasts, may be useful constituents for the maintenance of the correct intercellular communications required by the immune response.

accessory cells can be pre-prepared as a monolayer (Figures 4 and 5), when their application in cocultures with lymphocytes can reduce programmed cell death to <20%.

Nevertheless, immune responses *in vitro* can be effected without accessory cells. The key to success is to ensure efficient interaction between the appropriate mononuclear cell subpopulations shown in Figure 1. How this can be achieved will be dealt with in the following sections.

Enrichment of cells for immune responses *in vitro*

Separation of mononuclear cell subpopulations has been successfully applied to increasing the efficacy of immune response systems *in vitro*. The simpler methods make use of the differential adherence of leukocyte populations. T lymphocytes can be separated by the preferential binding of B lymphocytes and monocytes to nylon wool, although some T lymphocytes may also display a degree of adherence.

Antigen-presenting cells (APCs) can be enriched from lymphocytes by their differential adherence to plastic or Sephadex G10 (there may be some retention of B lymphocytes by such resins). The antigen-presenting dendritic cells can be selected from other monocytic cells through their differences in both adherence and density.

These relatively simple methods are not absolute for separating leukocyte populations. In contrast, the T cell rosetting method can enrich to a higher degree, although not all animal species possess T lymphocytes capable of binding sheep erythrocytes, via the CD2 molecule on the lymphocyte surface. Particularly specific enrichment or removal of leukocyte populations employ monoclonal antibodies against markers on leukocytes, in association with panning or cell sorting. For panning, antibody specific for a certain marker is bound to a plastic surface or Sephadex column, to which cells carrying the marker become immobilized. With cell sorting, the cells are first labeled with the antibody, followed by a magnetic bead or fluorochrome-labeled anti-mouse

Figure 2 Antigen presentation by the APC to T_H and T_C lymphocytes, showing the relevance of MHC class I and class II expression, as well as adhesion molecule interactions, in these processes.

Table 2 Examples of cytokines which have been successfully employed for *in vitro* immune response systems, either individually or in combinations, such as in 'cytokine soups' from mitogen-activated mononuclear (lymphocytes plus monocytes) cultures

Cytokine	Common sources	Known influences with <i>in vitro</i> immune responses
IL-1	Activated monocytic cells, fibroblasts, endothelial cells	Cofactor for T lymphocytes and antigen-stimulated B lymphocytes
IL-2	Activated T _H lymphocytes	Differentiation factor for antigen-stimulated B lymphocytes; T lymphocyte growth factor
IL-4	Activated T _H lymphocytes	Cofactor for T lymphocytes; differentiation factor for B lymphocytes (important in isotype switching); enhances APC activity
IL-5	Activated T _H lymphocytes	Differentiation factor for B lymphocytes (important in isotype switching); cofactor with IL-2 for B lymphocytes
IL-6	Activated monocytic cells, T _H lymphocytes	Cofactor for B and T lymphocytes; differentiation factor for B lymphocytes (differentiation into plasma cells)
Interferon γ	Activated monocytic cells, T _H lymphocytes	Cofactor with IL-2 for antibody secretion by B lymphocytes; regulator of T lymphocyte growth

conjugate; separation from unlabeled cells employs a magnet or a fluorescence-activated electrical field. Examples of markers commonly used are CD14 on myeloid cells (not all dendritic cells are CD14⁺), surface immunoglobulin on B cells, and CD2, CD4 or

CD8 on T lymphocytes (the latter two will be useful for separating T lymphocyte subpopulations); the T lymphocyte CD3 is not employed, because antibody reaction with this marker can stimulate the cells. An additional modification to the procedure employs

Figure 3 Accessory endothelial cell interaction with T lymphocytes and monocytic APC, via adhesion molecules and their ligands.

Figure 4 Summary of the methods employed for the preparation of mononuclear cells from lymphoid organs and the blood. These sources of mononuclear cells can be used for the preparation of APCs, or for the cultures to be stimulated by antigen in the immune response *in vitro*.

Figure 5 Summary of the preparation of preformed monolayers of accessory cells, and their application to coculture with mononuclear cells in immune response systems *in vitro*.

complement-mediated lysis to deplete unwanted cells: the antibody-labeled cells are treated with rabbit anti-mouse immunoglobulin and complement to induce the lysis.

A decision about whether or not to employ enrichment will depend on the required use of the *in vitro* immune response. Enrichment is not always essential. Its application should be carefully considered in the context of how beneficial it would be to the objectives of the experimentation.

Primary immune responses *in vitro*: general considerations

Mononuclear cell cultures derived from secondary lymphoid organs are preferable, in general, to blood cell cultures. Within the former, the cell populations required for an immune response are correctly represented, whereas blood mononuclear cells have a greater dominance of T lymphocytes, and an important population of suppressor cells. The latter can be impaired, unless they are the subject of interest, using agents such as leucyl methyl esters,

although not all species possess cells with equal sensitivity to such treatments.

The expected concentration of antigen-reactive lymphocytes within a primary immune response *in vitro* will be not more than $1 \text{ in } 10^6$. Considering the required cellular interactions, and that conventional cultures employ between 2×10^6 and 2×10^7 leukocytes ml^{-1} , this low concentration of potentially reactive cells does not lend itself to success. Enrichment procedures have been particularly useful in circumventing this problem. The potential also exists to apply hollow fiber or similar capillary culture vessels, wherein cell concentrations can be maintained at 10–1000 times that in conventional culture systems. Nevertheless, the methods which have found the widest application are the use of exogenous cytokines and the preprocessing of antigen. These techniques, which will be dealt with in the next section, have the advantage over enrichment procedures in that the balance of leukocyte populations within a mononuclear cell preparation has not been modified.

Initiation of the primary immune response *in vitro*

Cytokine application

With the immune response *in vitro*, B lymphocytes will be directly stimulated by antigen, whereas T_H lymphocytes must await antigen processing. This can result in stimulated B lymphocytes requiring T lymphocyte help before it is available. A relatively simple solution is to apply, at the moment of immunization, the cytokines required by the B lymphocyte differentiation pathway (Figure 6; Table 2), the stimulated T_H lymphocytes providing cytokines later in the response. Exogenous cytokines can be in two forms: recombinant cytokines (Table 2), or a 'cytokine soup' derived from a mixed leukocyte reaction (MLR) or mononuclear cell cultures stimulated with mitogen. Not all cytokines are available in recombinant form, nor for all animal species. Furthermore, cytokine soups should provide all the required factors, not just some of them. The drawback with the

cytokine soups is the variation between batches, due to variations in the responsiveness of different batches of mononuclear cells. Consequently, large batches of cytokine soups are normally prepared and pretested for their capacity to support an immune response.

Additional enhancement factors may be employed, such as β_2 -mercaptoethanol. This appears to function by interacting with serum components, which in turn have an influence on the B-T lymphocyte interaction. An important overall effect is enhancement of the generation of antibody-producing cells.

Antigen processing and presentation

An alternative approach would be to equilibrate the initiation of the B and T_H lymphocyte stimulations by preprocessing antigen. This uses cultures of APCs, MHC matched with the mononuclear cells to be employed. The APCs can be enriched (Figure 4) or irradiated mononuclear cells from secondary lymphoid organs without enrichment, the latter at high cell

Figure 6 The primary immune response system *in vitro*, showing the application of exogenous cytokines and the use of antigen preprocessing. The source of the mononuclear cells is usually a secondary lymphoid organ.

concentrations (10^7 ml^{-1}) to ensure the availability of the APCs. Antigen is fed to the APCs, usually 24–48 h before addition of the mononuclear cells to be stimulated plus fresh antigen (Figure 6). The T lymphocytes will be stimulated by the processed antigen on the APCs, and B lymphocytes by the fresh antigen (Figure 6). It is also possible to mix enriched T lymphocytes with APCs at the time of antigen addition, followed after 3–6 days with freshly prepared B lymphocytes, enriched or not. With such methodologies, it may be necessary to ascertain that the presence of the T lymphocytes in culture before APCs have processed the antigen will not be detrimental to these lymphocytes. Both techniques involving antigen processing have the advantage that exogenous cytokines are no longer necessary. Measurement of primary immune responses *in vitro* most often employs lymphoblast proliferation, although antibody production by B lymphocytes may be detectable if the antigen is particularly potent (Figure 6).

Choice and use of antigen

Primary immune responses *in vitro* require antigen to be particularly immunogenic. Examples are hemocyanin, ovalbumin and sheep erythrocytes, all of which have proved useful for studying aspects of the immune response *in vitro*, as opposed to specific antigen-related topics. Other antigens, such as viruses and bacteria, often require the assistance of exogenous cytokines or antigen processing before a primary response *in vitro* can be induced (Figure 6). Such procedures have found favor with *in vitro* primary immunization towards lymphoblast production for hybridoma generation. The preprocessing of antigen enhances lymphoblast differentiation and survival, while exogenous cytokines influence the isotype of subsequently produced antibody. It is currently considered that the employment of both of these events would be beneficial to the generation of antigen-specific hybridomas from *in vitro* immune responses.

Secondary immune responses *in vitro*: general considerations

Both secondary lymphoid organs and blood can be sources of mononuclear cells for secondary immune responses (Figure 7). The suppressor cell problem within blood mononuclear cells is less apparent, or critical, with secondary responses, and may not require prior inhibition. Nevertheless, lymphoid organ cells have been the more widely applied in secondary immune responses *in vitro*.

Not all problems encountered with the primary response *in vitro* are found with secondary response

Table 3 Advantages of employing secondary compared to primary immune responses

Increase in relative concentration of antigen-specific lymphocytes
More rapid induction of T_H lymphocyte proliferation
More rapid induction of T_H lymphocyte cytokine production
Enhanced efficiency of T_H lymphocytes in delivering their immunological help
Reduced obligation for preprocessing of antigen
Reduced obligation for exogenous cytokine addition
Requirements for 'enhancement factors' less likely
Absence of accessory cell function less of a problem
<i>In vitro</i> immune response system can be simple – mononuclear cells plus antigen
Increased manipulability of the immune response system, facilitating studies on accessory cell and cytokine involvement in the immune response

systems. Secondary response systems have a number of advantages (Table 3) relating to memory cell development, wherein memory antigen-specific lymphocytes can be of the order 1 in 10^3 to 1 in 10^4 within a lymphocyte preparation. Nevertheless, the cell concentration – $1\text{--}4 \times 10^6$ lymphocytes ml^{-1} – in the secondary immune response *in vitro*, and thus programmed cell death, are still potential problems. Accessory cells can assist in this direction (Figures 1, 3 and 5), but the secondary response can be effected in their absence. In contrast, application of accessory cells to general analyses of the secondary response can be informative, especially in the area of intercellular communication. Enrichment of cell subpopulations can also be applied to secondary immune responses, often but not always to study the roles played by the enriched cells (Figure 7). However, secondary immune responses *in vivo* do not require such manipulations.

Initiation of the secondary immune response *in vitro*

Cytokine application

Neither exogenous cytokines nor preprocessed antigen are obligatory for secondary immune responses *in vitro* (Figure 7). When applied, it is usually to study their influence on the immune response. These characteristics relate to the more efficient capacity of memory T lymphocytes to respond after antigenic stimulation, produce cytokines, and interact with B lymphocytes. The response is further assisted by the B lymphocytes presenting antigen to memory T lymphocytes.

Figure 7 The secondary immune response system *in vitro*, showing that antigen preprocessing by APCs may be employed, but is not essential. The mononuclear cell preparations can be from lymphoid organs or blood, and enrichment of particular populations may also be employed.

Antigen processing and presentation

Despite the more efficient capacity of lymphocytes to respond during a secondary immune response *in vitro*, preactivation of T lymphocytes is a commonly employed procedure. Cultures may simply be mononuclear cells, or alternatively enriched populations. With enrichment, a source of APCs must be ensured: irradiated mononuclear cells or enriched dendritic cells can be employed (Figure 7), although the capacity of memory B lymphocytes to function as APCs should also be considered. In experiments employing enrichment, antigen is often applied 3–6 days before B lymphocytes are added (Figure 7); fresh antigen may be unnecessary, dependent on the antigen and characteristics of the memory lymphocytes in the culture. When nonenriched mononuclear cell cultures are employed, antigen is added at the initiation of the experiment (Figure 7). Measurement of secondary immune responses *in vitro* often employs T lymphocyte proliferation or antibody production by activated B lymphocytes (Figure 7).

Choice and use of antigen

Secondary immune responses *in vitro* have been applied to studies employing antigens of, for example, viruses, bacteria and peptides of known sequence or structure. The applicability of the procedures is evident from the studies on peptide antigens, which have been applied to analyses of B lymphocyte and, in particular, T lymphocyte responses. Not all peptide antigens are equally immunogenic. Certain may require costimulation with interleukin 2 (IL-2), followed by restimulation with the peptide antigen before lymphocyte proliferation is detectable. Similar restrictions may apply to certain more complex antigens, but will depend on both the antigen and the capacity of the constituent mononuclear cells in an *in vitro* culture to respond.

Additional applications particular to secondary immune responses *in vitro*

Secondary immune responses *in vitro* have also been applied to studies on intercellular communications.

Cultures of mononuclear cells have been employed for analyses of lymphocyte/monocyte and lymphocyte/lymphocyte interactions. Cocultures of mononuclear and endothelial cells are often used to study the role of the endothelial cells. Both types of culture, as well as those with enriched subpopulations or cell lines, have assisted in the identification of adhesion molecule and cytokine activity. Cultures employing enriched subpopulations have been particularly useful in identifying the roles of these subpopulations in the immune response, especially with respect to intercellular communications and interactions.

Concluding remarks

The potential to effect immune responses *in vitro* has advanced rapidly over the past 25 years. Analyses have demonstrated the complexity of the immune response, studies having taken two main forms: initial *in vitro* experimentation, from which subsequent *in vivo* analyses were designed; observations from *in vivo* experimentation studied further by *in vitro* means, in a detail not otherwise possible. The *in vitro* immune response systems have permitted a controlled analysis of the compartments and factors involved *in vivo*. Application of *in vitro* systems has also permitted a reduction in the usage of animals. The areas which have profited most from immune responses *in vitro* have been the generation of hybridoma and T lymphocyte cell lines, and the studies on immune responses *per se*. These latter studies have increased and will continue to increase the level of understanding of the immune system and the constituent responses.

IMMUNE SURVEILLANCE

Gert Jan Fleuren and **Arko Gorter**, Department of Pathology, Leiden University Hospital, Leiden, The Netherlands

Peter JK Kuppen, Department of Surgery, Leiden University Hospital, Leiden, The Netherlands

Evolution has supplied us with an immune system capable of dealing with pathogenic microorganisms. Neoplasms may be recognized by the immune system either because the molecular mechanisms evolved for recognition and elimination of pathogens are also coincidentally effective in the elimination of tumor cells or, because a primary function of the immune system is to survey the body for arising neoplasms. The beginning of this immune surveillance theory dates from 1957 when Burnet wrote: 'It is by no means inconceivable that small accumulations of tumor cells may develop and because of their possession of new antigenic potentialities provoke an effective immunological reaction with regression of the tumor and no clinical hint of its existence'.

The immune surveillance theory states that the immune system is constantly monitoring the body for the appearance of tumor cells, and that the majority of these aberrant cells are destroyed by the immune system before giving rise to clinically manifest tumors. If the concept of immune surveillance is correct and fully applicable, all tumor cells which arise will be immunogenic and the immune reaction induced by these cells prevents the outgrowth of a tumor. The presence of clinically detectable tumors in immunocompetent individuals, however, indicates that mechanisms have evolved to escape elimination. Examples of escape mechanisms are: antigenic modulation (e.g. HLA downregulation), antigen masking, production of soluble tumor antigens or other tumor products (e.g. transforming growth factor β , TGF β), induction of tolerance and weakening of the defense system itself.

History of the immune surveillance theory

At the end of the nineteenth century, tumor biologists started to study allogeneic tumor growth in animals upon transplantation. Observations in 1902

by Jensen and Ehrlich on tumor rejection tempted Ehrlich to suggest a role for the immune system in the control of tumor growth. However, attention for this idea soon faded as it became known that transplant rejection or acceptance was merely a consequence of genotypic variation between host and donor rather than of a specific antitumor response. The interest in tumor immunology revived around 1950 with the introduction of inbred animal strains creating a tool to study tumor rejection in genetically identical animals. From then on proof accumulated for a role of the immune system in the eradication of tumors. In 1959, stimulated by the ideas of Thomas and others, Burnet postulated the immune surveillance theory.

At present, malignant tumors are believed to arise as a result of a series of specific genetic events which include the activation of oncogenes and the loss of function of tumor suppressor genes. A large array of control mechanisms are operative within a cell to prevent abnormal growth (e.g. DNA repair mechanisms, tumor suppressor genes and apoptosis of irreversibly damaged cells). If these control mechanisms are no longer operative, cells continue to proliferate. Subsequently, a dynamic interaction of the malignant phenotype with its microenvironment (including the immune system) occurs, which may result in tumor progression. Thus, in addition to the genetic properties of aberrant cells, the microenvironment will also determine survival or death of malignant cells (Figure 1).

It is assumed in the immune surveillance theory that immunocompetent individuals eradicate tumor cells before tumors become clinically detectable. Therefore, it is difficult to obtain indisputable evidence regarding the validity of the immune surveillance theory. One should always be aware that the arguments either in favor or opposing the theory (Table 1) are extrapolated from observations of established tumors.

Figure 1 Schematic representation of the development of a normal cell into a tumor cell.

Experimental and clinical observations supporting the immune surveillance theory

Primary immunodeficiency

In all species cancer is mainly associated with old age, being from about 2 years in mice to about 70 years in humans. Older mice have been found to be less resistant to xenogeneic, allogeneic and syngeneic tumor cells than younger mice. These observations may indicate involvement of the immune system in

prevention of tumor development, as the immune system becomes less effective with increasing age. Immunodeficient animals show a higher frequency of virus-induced and chemically-induced tumors.

Natural killer (NK) cells, part of the first line of defense as they are able to kill cells without prior sensitization, are presumed to play an important role in immune surveillance. Mice with genetically determined low levels of NK cells, beige mice, display an increased incidence of spontaneous tumors and a lower natural resistance to syngeneic leukemias. Furthermore, nude mice which have no functional T cells but normal NK cells do not show an increased incidence of tumors in general, but only of virus-induced tumors, indicating a role for T cells in immune surveillance of the latter tumor types and for NK cells in the other types of tumors.

In agreement with the observations in immunodeficient animals, in immunodeficient patients a higher cancer incidence is also observed. Humoral deficiencies, such as X-linked agammaglobulinemia and common variable immune deficiency, and cellular immunodeficiency syndromes, such as Wiskott-Aldrich syndrome, ataxia telangiectasia, the X-linked

Table 1 Clinical observations with explanations related to the immune surveillance theory

Observation	Explanation	
	In favor	Opposing
Tumors are clinically present	Tumor cells escape from immunological control	Tumor cells are not immunogenic
Increased tumor incidence in immune deficiency, especially non-Hodgkin lymphomas and squamous cell carcinomas	Impaired immunological control Accumulation of multiple hits in common tumors is a slower process as compared to tumor induction in virus-associated tumors	The presence of malignancies is due to (genetic) dysregulation of the cells, carcinogenic properties of immunosuppressive drugs, transformation of cells due to viruses, or predisposition of cells due to increased incidence of viral infection
Spontaneous regression of tumors	Elimination of tumor cells by the immune system	Destruction of tumor cells due to other than immunological causes (e.g. insufficient blood supply)
Regression of non-Hodgkin lymphoma after drastically decreasing immunosuppressive therapy	Recovery of a functional immune system resulting in elimination of tumor cells	Immunologic destruction due to the presence of EBV in the majority of these tumors
Increased tumor incidence with age	Decreased T cell function (coinciding with involution of the thymus)	Carcinogenesis requires multiple genetic hits which accumulate with age
Long latency in the appearance of secondary tumors	Struggle of the immune system with tumor cells	Latency due to environmental factors or necessity for additional genetic hits
Immune cells are associated with tumors	Tumor cells induce an immune response	Dead tumor cells evoke a chronic inflammatory response
Tumor regression after immunotherapy	Tumor cells induce an immune reaction	Tumor cells occasionally induce an antitumor reaction, depending on the antigens locally presented

lymphoproliferative syndrome, and the Chédiak-Higashi syndrome, are associated with an increased chance of developing cancer, especially non-Hodgkin lymphoma.

Secondary immunodeficiency

Among the acquired immunodeficiencies, information regarding immune surveillance can be obtained from those instances where the immune system is depressed either due to drugs (azathioprine, corticosteroids or anti-T cell antibodies (OKT3)) used in tissue transplantation, or due to infection with microorganisms (e.g. human immunodeficiency virus (HIV) or malaria). An increased incidence in malignancies has been reported in kidney, liver and heart transplant patients. Most data are available from kidney transplant patients. In these patients generally skin cancers (squamous cell carcinomas) and non-Hodgkin lymphoma have been reported to be increased. Interestingly, if malignancies develop in patients with tissue transplants, a drastic reduction in the administered dose of the immunosuppressive drug results in a clinical remission in approximately 25% of the cases, suggesting that recovery of immune function results in eradication of tumor cells.

In immunosuppressed patients due to malaria an increased incidence of Burkitt's lymphoma has been observed. In patients with the acquired immune deficiency syndrome (AIDS), primarily Kaposi's sarcoma and non-Hodgkin lymphoma are present, whereas among women with AIDS an increase in cervical carcinoma is noted.

Spontaneous regression of tumors

The clinical observation of spontaneous regression of tumors also supports the immune surveillance theory. An inverse relationship between the prevalence of the tumor type and the probability of spontaneous regression is observed. Of all the cases reported, the majority comprise malignant melanoma, renal cell carcinoma, lymphoma, leukemia, neuroblastoma and retinoblastoma. The reports on spontaneous regression also include the observation that metastases might disappear after resection of the primary tumor, a phenomenon called concomitant immunity. Remissions have been associated primarily with infection, surgery or trauma. These impairments may have (re)activated the immune system, resulting in tumor regression.

Also the observation that metastases reappear after long latent periods, e.g. patients with breast cancer, malignant melanoma, neuroblastoma and leukemia, may support the immune surveillance theory. The latency in tumor growth observed can

be explained as a struggle between the immune system and tumor cells.

Tumor-infiltrating cells

Microscopical examination of tumor biopsies shows that tumors are surrounded or infiltrated by immune cells. Generally, T cells and macrophages are abundantly present in human tumors, suggesting an immune response directed against the tumor cells. Indeed T cells directed against autologous tumor cells have been isolated from several tumor types, e.g. malignant melanoma, renal carcinoma and cervical carcinoma. These T cells either recognize peptides presented in the context of HLA class I from genes which are silent in most other cell types, like MAGE in malignant melanoma, overexpressed proteins (e.g. p53), or peptides derived from mutated (e.g. ras) or truncated proteins. Also, antibodies directed against tumor-associated antigens can be demonstrated in cancer patients. Thus, there is strong evidence that tumor cells can induce an immune response *in vivo*.

Immunotherapy of cancer

Infusion of cytokines, autologous *in vitro* IL-2 stimulated lymphocytes obtained from the peripheral blood of cancer patients, or tumor-infiltrating lymphocytes occasionally results in a complete remission, notably in patients with neuroblastoma, renal cell carcinoma, or malignant melanoma. This observation suggests that an immune response can be elicited against these tumor types.

In summary, as stated by Burnet, it is conceivable that small accumulations of tumor cells develop and that aberrant tumor cells evoke an immune response resulting in the eradication of these cells. However, it is at present neither clear whether *all* tumor cells are able to evoke an immune response nor whether the presence of established tumors represents escape from immunological control.

Alternative explanations for the phenomena assigned to the immune surveillance theory

Those being skeptical with regard to the immune surveillance theory refer to the alternative explanations for phenomena such as increased tumor incidence in immunodeficiency, spontaneous regression of tumors, and the association of tumor cells with cells from the immune system.

Tumor incidence associated with immunodeficiency

Alternative explanations regarding the increased

tumor incidence in immunodeficiency are also entirely plausible. The increased tumor incidence in immunodeficient renal transplant patients is primarily due to an increase in skin cancer (squamous cell carcinoma) and non-Hodgkin lymphoma (the majority being of B cell origin), whereas a substantial increase in the more common cancer types, such as breast cancer, cancer involving the respiratory system, and gastrointestinal cancer, is not observed in these patients. Non-Hodgkin lymphoma and skin cancer in immunodeficiency are associated with a viral etiology (Epstein-Barr virus (EBV) and human papillomavirus (HPV), respectively). It is therefore conceivable either that these viruses are carcinogenic themselves or that the increased frequency of viral infection acts as a cofactor, making the infected cell vulnerable to becoming a tumor cell. With regard to immunosuppression, it should be noted that only parts of the immune system are immunosuppressed (generally the T cell compartment). Similarly, the increased incidence of non-Hodgkin lymphoma in patients with congenital immune deficiencies might be due to an abnormal proliferative response (regulation) of the immune cells, due to genetic aberrations in these patients.

Immune suppressive drugs may also cause the anomalies observed. Patients treated for longer periods with cyclosporine or azathioprine were shown to have chromosomal abnormalities. Immunosuppressive drugs may also have synergistic effects to other carcinogens. Metabolites of azathioprine cause chemical photosensitization. A synergistic effect of azathioprine with ultraviolet light or HPV may explain the high incidence of skin cancer in allograft recipients.

Spontaneous regression of tumors and latency

Because of a lack of knowledge regarding the etiology of spontaneous remissions, such remissions could be associated with a variety of causes (e.g. vascular insufficiency, tumor differentiation or psychosomatic mechanisms) in addition to immunological phenomena. The presence of long latency periods before metastases appear may equally well be due to environmental factors (e.g. lack of adhesion molecules or growth factors), the absence of additional genetic 'hits' required for tumor progression, as to immune mechanisms.

Tumor-infiltrating cells

The observation of an infiltrate of immune cells surrounding tumor cells might be due to a chronic inflammatory response initiated and sustained by cell death. During this process, only occasionally (depending on the proteins expressed by the tumor

cells) does an antitumor response occur. This occasional immunogenicity of the tumor cells may also explain the limited successes of immunotherapy of cancer.

In conclusion, inherent with the nature of the theory that neoplasms are eradicated before becoming clinically evident, formal proof either in favor or against the immune surveillance theory is difficult to obtain. It is proven beyond doubt that the immune system is able to mount an immune response against particular tumor cells. However, one can still argue whether all tumor cells which arise are immunogenic, and if an immune response occurs each time tumor cells arise.

IMMUNE SYSTEM, ANATOMY OF

CE Grossi, National Institute for Cancer Research, University of Genoa, Genoa, Italy

PM Lydyard, Department of Immunology, University College London Medical School, London, UK

Cells participating in the immune response are organized into discrete lymphoid tissues and organs and spread through the connective tissues of non-lymphoid organs. The cell type responsible for the specificity of the immune response is the lymphocyte. Approximately 2×10^{12} lymphocytes constitute the mature lymphoid system in humans together with a variety of 'accessory' cells which include epithelial cells, monocyte/macrophages and other antigen-presenting cells. Accessory cells are required both for the maturation and for the effector functions of lymphocytes.

Lymphocytes are derived from hematopoietic progenitors which mature within the bone marrow (and the fetal liver) giving rise to B lymphocytes, or seed to the thymus where they differentiate into T lymphocytes. The bone marrow and the thymus are therefore the primary or central lymphoid organs. Mature lymphocytes leave the central organs via the blood vessels, and migrate to secondary or peripheral tissues and organs where they exert their effector functions in response to antigen. Peripheral lymphoid tissues include the spleen and lymph nodes (Figure 1) and MALT (mucosa-associated lymphoid tissue) which is associated with the respiratory, genitourinary and gastrointestinal tracts (Figure 2), accounting for approximately 50% of the total lymphoid cells in the body.

Central lymphoid organs

The bone marrow, and earlier in fetal life, the liver, and the thymus provide the microenvironments for the differentiation of B and T lymphocytes respectively, and for the production of mature cells responsible for humoral or cellular immune responses. During B and T cell maturation, similar events occur in the bone marrow and in the thymus, namely the rearrangement of the genes encoding antigen receptors (immunoglobulin (Ig) or T cell receptors (TCRs)) and the expression of these receptors on the

Figure 1 Major lymphoid organs and tissues.

cell surface. A variety of other cell surface 'marker' molecules appear in an orderly sequence which defines the maturational stages of both B and T cells.

The bone marrow provides the microenvironment for B lymphocyte differentiation. This process takes place through the direct interaction of B cell progenitors with ill-defined 'stroma' cells and with the help of soluble factors, notably interleukin 7 (IL-7), which supports the growth of pre-B cells and possibly of their progenitors.

The thymus provides the microenvironment for differentiating bone marrow-derived precursors seeding into the epithelial rudiment during ontogeny. The complete sequence of maturational events leading to the production of mature T cells takes place within this organ. Maturing T cells interact with nonlymphoid thymic cells, namely epithelial cells and

Figure 2 The mucosa-associated lymphoid system.

macrophages/interdigitating cells. Intrathymic T cell maturation results from these cellular interactions and from the resulting cytokines (IL-1, IL-2, IL-6) produced by them. The major events that occur in the thymus are proliferation and the positive and negative selection of T cells. Thymocyte proliferation leads to polyclonal expansion of T cells and is the result of a direct interaction between thymocytes and epithelial cells. Positive selection favors the expansion of those cells equipped with TCRs that have proven able to bind self MHC molecules weakly, even in the absence of antigen. Those developing T cells which display the best fit between their TCRs and class I and class II MHC molecules expressed by nonlymphoid thymic epithelial cells have a growth advantage. Negative selection implies the elimination of self-reactive T cell clones upon encounter with self antigens during intrathymic maturation. It is generally believed that negative selection takes place following interaction of the more mature thymocytes with interdigitating cells present in the thymic medulla.

Mature B and T cells leave the central organs and migrate to the peripheral lymphoid tissues.

Peripheral lymphoid organs

The effector functions of B or T cells responsible for humoral or cell-mediated immune responses are carried out in the lymphoid periphery which consists of discrete organs or foci of lymphoid tissue, and of

lymphocytes dispersed in the interstitial areas of non-lymphoid organs (e.g. liver, lung and the lamina propria of mucosae). The peripheral lymphoid tissues possess a vascular and cellular organization which favors the encounter the antigens and antigen-presenting cells with mature B and T lymphocytes. The frequency of appropriate encounters between antigens and cells bearing specific antigen receptors is increased by the active recirculation of lymphocytes via blood and lymph vessels. Thus, the structural organization of peripheral lymphoid tissues is dynamic, with actively renewing mature cell populations supported by the thymus and bone marrow.

In addition to the lymphocytes which constitute the major cell component of the lymphoid tissues, monocyte/macrophages and other antigen-presenting cells of the same lineage (such as dendritic cells, interdigitating cells, veiled cells, etc.) play an essential role in the initiation and development of the immune response. Many of these 'accessory' cells are also able to migrate from skin and mucosae to draining lymph nodes in order to accomplish their function as antigen 'carriers' and 'presenters'.

Mature B and T lymphocytes migrate from the central organs into distinct areas of the peripheral lymphoid tissues, namely the B-dependent and T-dependent zones. Encounter with antigen initiates proliferation, activation and differentiation events leading to the generation of effector cells and memory cells. The effector cells for humoral immune responses are the antibody-secreting plasma cells. T helper and T cytotoxic cells are the effector cells for cell-mediated immune responses. Effector and memory cells are found in distinct areas within the peripheral lymphoid tissues. For example, plasma cells are present in the spleen red pulp and in the lymph node medullary cords, whereas memory B cells are located in the germinal centres of the secondary lymphoid follicles in splenic white pulp, lymph node cortex and MALT.

Antigens can penetrate the natural barriers provided by the skin and mucosal surfaces, or they can enter the blood circulation directly. To ensure appropriate protection, peripheral lymphoid organs (lymph nodes) are strategically located along the lymphatic vessels draining the skin and mucosal areas of the body and defend the external and internal body surfaces. The spleen combats blood-borne antigens. Antibodies produced in the spleen and lymph nodes are usually detectable in the serum. The type of protection which is provided by these organs is usually referred to as systemic immunity.

The mucosa-associated lymphoid tissue forms a functionally distinct line of defense (see **Figure 2**). The MALT consists of aggregates or foci of

lymphoid tissue which are found in the lamina propria and in the submucosa of several mucosal membranes of the digestive, respiratory, urinary and genital tracts. The size of these lymphoid aggregates varies from that of microscopically detectable solitary lymphoid nodules to larger accumulations such as those of the tonsils, Peyer's patches and appendix. The same compartmentalized B and T cell-dependent zones described for the spleen and lymph nodes occur in the MALT. However, one notable feature of the latter is the close association of the lymphoid tissue with the mucosal epithelium. Epithelial cells overlaying the lymphoid aggregates can take up antigens present in the lumen (or adhering to the mucosal surface) and transport them to the underlying lymphocytes. Furthermore, epithelial cells play an active role in the transport and secretion of locally produced IgA antibodies into the lumen. In fact, antibodies produced at the mucosal level are predominantly of the secretory kind.

Another important feature of the MALT is the frequent presence of lymphocytes within the epithelium (intraepithelial lymphocytes, IELs). Most IELs are of T lineage and some of them express $\gamma\delta$ TCRs. It is possible that these cells provide a line of defense at the epithelial level through cell-mediated immune responses. Therefore, it appears that the MALT represents a system which is quite distinct from that responsible for the systemic immunity and which accounts for mucosal immunity.

The distinction between systemic and mucosal immunity is further reinforced when certain features of lymphocyte trafficking are considered in the two systems. Lymphocytes circulate via blood and lymph vessels which provide the major routes for their seeding from central to peripheral organs and for their migration amongst the peripheral lymphoid organs, respectively. Circulation and homing of lymphocytes is determined and regulated by their ability to interact with endothelial cells. This interaction occurs primarily with the endothelium of high endothelial venules (HEVs), a special type of postcapillary venules. These vessels are found mainly in the T-dependent areas of the peripheral lymphoid tissues, but also in other tissues including the MALT and thymus. Endothelial cells may be activated and alter their shape, structure and receptor expression to become high endothelial cells in sites of inflammation

such as the synovium in patients with rheumatoid arthritis. A number of molecules are expressed by activated endothelial cells and include members of the immunoglobulin superfamily, e.g. ICAM-1 (CD54) and VCAM-1 (CD106), and selectin family, e.g. E-selectin (ELAM: CD62E) and P-selectin (CD62P). Lymphocytes bind to endothelial cells through surface molecules collectively grouped in the CD44 antigen family (previously designated as Hermes, Pgp-1, gp80–95). Integrins expressed by lymphocytes (such as LFA-1) are also involved. Interactions between lymphocyte CD44 or integrins and adhesion molecules on endothelial cells trigger the subsequent events that regulate the migration of lymphocytes between adjacent endothelial cells.

There appears to be some degree of selectivity in the interaction between lymphocytes and endothelial cells. Adhesion molecules expressed by some lymphocytes ($\alpha_4\beta_7$ -integrins) will be recognized and interact with 'addressins' (e.g. MAdCAM-1) expressed by the HEV endothelial cells in Peyer's patches. MAdCAM-1 is not expressed by endothelial cells in spleen and lymph nodes. It therefore follows that migration of lymphocytes from the circulation into the peripheral lymphoid tissues is not just random but is specifically directed. In support of this notion it has been shown that B lymphocytes primed in the intestine can migrate to other regions of the MALT. These cells can differentiate into plasma cells and produce antibodies detectable in the saliva or in the milk produced by the lactating mammary gland. Thus, the selective trafficking of lymphocytes appears to provide additional support for the distinction between a systemic and a mucosa-associated immune system.

IMMUNOADSORBENTS

Richard E Ostlund Jr, Metabolism Division, Washington University
School of Medicine, St Louis, Missouri, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Immunoabsorbents are specific antibodies attached chemically to solid supports. The antigen of interest contained in a crude mixture is bound noncovalently to the immunoabsorbent, after which it can either be discarded (when unwanted materials must be removed) or isolated after treatment of the sorbent–ligand complex with a denaturing agent. Properties of immunoabsorbents depend critically on the methods used to prepare them. Both soluble antigens and intact cells can be bound and suitable sorbents are commonly employed in research and clinical treatment.

Solid supports

Antibodies can be immobilized simply by treating them with a cross-linking agent such as glutaraldehyde, but the resulting agglutinated material is not homogeneous and many of the reactive sites are either damaged or hidden. A more efficient method employs a solid support to which antibodies are chemically attached. Glass, silica, plastic and cellulose have been used but the most generally satisfactory support material is agarose, a polysaccharide prepared from uncharged fractions of agar. Agarose has also been used to encapsulate immunoabsorbents made from other materials as it is highly biocompatible. It is supplied in the form of hydrated porous spheres 40–300 μm in diameter containing 2–8% agarose by weight in aqueous solution. Agarose is resistant to degradation by enzymes from most bacterial strains and by chemical agents, and after internal cross-linking by treatment with epichlorohydrin or similar agents it can be autoclaved in 1 N

sodium hydroxide allowing for both sterilization and depyrogenization. Agarose can be hydrolyzed to simple sugars by overnight incubation in 3 N HCl at 80°C but is resistant to 1 N acids at ambient temperature.

Immunoabsorbents are traditionally constructed from high resolution small agarose beads approximately 100 μm in diameter, such as Sepharose 4B (Pharmacia-LKB). However, for use in immunoabsorbents larger beads of 212–300 μm work equally well and have much better flow properties, being very resistant to plugging and useful even with undiluted plasma, whole blood or dispersed cells. The sorbent capacity is a function of the percent agarose content and is highest between 2 and 6% agarose; some ligands may experience greatly increased binding on immunoabsorbent beads of 2% agarose.

Coupling antibody to agarose

Sorbent beads must be activated in order to bind antibody molecules. Generally the agarose is first reacted with a bifunctional cross-linking reagent yielding an agarose linker with one remaining functional group. This activated agarose is then added to a solution of the antibody to be coupled. Table 1 summarizes the results obtained with various coupling chemistries applied to one antigen–antibody system. While all methods tested give good coupling of antibody to agarose, there are large differences in the ability of the immunoabsorbents to bind antigen. The highest activity was achieved with the cyanogen bromide technique, a finding noted with other antigen–antibody systems which has caused it to remain popular despite the toxicity of its reagents and the

Table 1 Comparison of methods for preparing immunoabsorbents. Activated gels of 4% cross-linked agarose were reacted with saturating amounts of affinity-purified goat antihuman low density lipoprotein antibody, and the amount of antibody coupled to agarose is shown in column 3. The immunoabsorbents were then reacted with a saturating amount of low density lipoprotein and the amount of low density lipoprotein reversibly bound and eluted by 1 M acetic acid is shown in column 4

Agent used to couple antibody to agarose	Stability	Maximum amount of antibody coupled (mg ml ⁻¹ agarose gel)	Maximum amount of ligand bound (mg ml ⁻¹ sorbent)
Cyanogen bromide	Moderate	4.9	4.3
2-Fluoro-1-methylpyridinium <i>p</i> -toluene sulfonate	Excellent	6.0	2.6
<i>N</i> -Hydroxysuccinimide	Moderate	10.1	2.5
Glutaraldehyde	Excellent	6.3	1.6
Trichlorotriazine	Excellent	12.0	0.7

relative instability of the linkage produced at extremes of pH. The instability is reduced considerably if internally cross-linked agarose is used and if the immunoadsorbent is washed with detergent, so that it is rarely a critical limitation.

The physical separation of agarose beads from chemically attached antibodies by interposition of long hydrophilic spacer arms theoretically allows greater conformational movement by the antibody, but in practice these spacers often make little difference to the performance of immunoadsorbents.

After coupling is complete unreacted sites are blocked by overnight incubation with a large concentration of a small molecular weight agent such as ethanolamine or glycine. Nonspecifically adsorbed antibody can be removed in two steps. First, ionically bound material is removed using several alternating pH 4 and pH 9 washes with buffer containing 0.5 M salt. Then hydrophobic bonds are disrupted by incubation in 1 M acetic acid for several hours, followed by treatment with neutral buffer containing a detergent such as 1% Liquinox or Triton X-100. Immunoadsorbents are usually stable to detergent treatment and this process will reduce leaching of noncovalently attached antibody from the sorbent during use. Much of the antibody release from immunosorbents originally thought to be due to chemical bond lysis is actually desorption of hydrophobically bound material, which can be reduced greatly by detergent treatment.

Use of the immunosorbent

The sample is best applied to the immunosorbent in batch by rotating end-over-end for approximately 2 hours. Washing and elution of the desired material is most conveniently done by pouring the gel into a column. The best general eluant is 1 M acetic acid (pH 2.3) applied with sufficient forward linear flow to elute the column over 0.5–3 hours. Elution of ligand in a batch process is sometimes ineffective. Alternative methods of immunosorbent elution use

alkaline buffers (pH 11) or chaotropic agents such as 3 M potassium thiocyanate.

Several factors limit the separations which can be achieved with immunoadsorbents. Although in theory a single substance will be isolated, immunoadsorbents are necessarily ion exchangers because of the charges on antibody protein and are also capable of hydrophobic interaction with unwanted components of the sample. These contaminants are released along with the desired antigen when the immunoadsorbent is exposed to denaturant. The separation achieved therefore depends on the concentration of the antigen of interest relative to contaminants prevailing before application to the immunoadsorbent. For example, specific antibodies isolated by immunoadsorbent from high-titer immune serum (which may contain 20% of the specific antibody) are nearly homogeneous, whereas immunoadsorbent preparations of nonabundant proteins from crude cell or tissue extracts are composed principally of contaminants. Thus, immunoadsorbents are useful as a single step in the preparation of abundant proteins, or helpful in conjunction with several other independent separation techniques in the multistep purification of nonabundant proteins. Antibodies may lose avidity and capacity for antigen after immobilization and this tends to accentuate the limitations noted.

Monoclonal antibodies

Effective sorbents can be made from monoclonal antibodies, but the antibody to be used needs careful selection, as illustrated in Table 2. Data are presented for two monoclonal antibodies, both of which bind efficiently to antigen in solution or on ELISA plates and are also coupled efficiently to agarose beads. However, immunoadsorbents made from the first antibody have ten times the antigen-binding capacity of those made from the second. In fact, immunoadsorbents prepared from the second antibody are nearly useless because of the small amount

Table 2 Example of variation in the suitability of monoclonal antibodies for use in immunoadsorbents. Anti-low density lipoprotein (LDL) antibody B1B3 was superior to antibody C3D1 in ELISA assays and in coupling to agarose beads. However, the C3D1-agarose immunoadsorbent was ten times more effective at binding LDL (right column)

Anti-LDL monoclonal antibody	LDL binding in ELISA assay ^a (mg LDL mg ⁻¹ antibody)	Antibody coupled to agarose beads ^b (mg ml ⁻¹ agarose)	LDL bound to immunoadsorbent (mg ml ⁻¹ sorbent)
C3D1	1.2	4.1	8.7
B1B3	3.5	5.1	0.7

^aData from Tikkanen MJ, Dargatzis R, Pfeiffer B, Gonen B, Davie JM and Schonfeld G (1992) Antigenic mapping of human low density lipoprotein with monoclonal antibodies. *Journal of Lipid Research* 23: 1032–1038.

^bCoupling of antibody to 2% agarose beads by means of cyanogen bromide.

of specific antigen binding. There is no general method for selection of antibodies for immunoadsorbents, but the potential for improved performance is clear.

Clinical applications

Immunoadsorbents are currently used in the preparation of drugs and biologicals and must not convey undue risk to humans who use the end-products. Disinfection, the elimination of vegetative bacteria, can be achieved with 1 M acetic acid or 70% ethanol used at room temperature for several hours, with retention of immunoactivity. In fact, in some cases treatment of agarose-immobilized immunoglobulins with ethanol actually increases the sorbent capacity. Immunoadsorbents become inactivated when autoclaved or exposed to ethylene oxide gas, but they retain 30–100% of activity after treatment with 1% peracetic acid, 2% glutaraldehyde, or 0.34% phosphoric acid in 80% ethanol, all of which are true sterilizing agents. Immunoadsorbents should be free of DNA for human use applications. Pyrogens can usually be removed by extensive detergent washing.

It is possible to use immunoadsorbents as artificial organs in clinical applications. For example, patients with homozygous familial hypercholesterolemia have extreme elevations of plasma low density lipoprotein (LDL) which can be removed extracorporeally by pumping plasma or even whole blood over sterile columns of anti-LDL agarose. This process is termed LDL-apheresis. Although the antigen–antibody complexes formed in the sorbent column activate complement, this can be suppressed by the use of citrate, a calcium complexing agent, as the anticoagulant.

Immunoglobulin-binding protein A sorbent columns have been used to treat a variety of immunological disorders. Bone marrow stem cells have been selected and purified by binding to immunoadsorbents prior to transplantation, demonstrating the feasibility of selecting for or excluding specific cells in a clinical setting.

IMMUNOASSAYS

RP Ekins, Division of Molecular Endocrinology, University College London Medical School, Mortimer Street, London, UK

Immunoassays fall within the broader class of techniques – frequently described as ‘binding assays’ – that rely on observation of the binding reaction between the analyte and a specific binding substance, the latter being generally of biological origin and typically comprising a specific binding protein. Antibodies constitute an especially important class of protein in this context, as they can be generated conveniently and in large amount (either by conventional *in vivo* methods or, more recently, by the *in vitro* techniques pioneered by Milstein and Köhler)

against an extensive range of substances of biological interest, including high molecular weight substances (e.g. proteins, polypeptides, viral particles, oligonucleotides, etc.) as well as substances of relatively small molecular size not themselves intrinsically immunogenic (‘haptens’), such as drugs, steroid and thyroid hormones, vitamins, etc. Naturally-occurring specific binding proteins nevertheless continue to be used in ‘protein binding’ assays, e.g. in assays for vitamin D and its metabolites, vitamin B₁₂, folic acid and (occasionally) thyroxine, albeit the availability

of specific antibodies against most of these substances has resulted in the progressive abandonment of the binding proteins as analytical reagents. More recently, binding assays essentially identical in principle to immunoassay, but relying on DNA 'probes' as binding reagents, have been introduced, although these are restricted in application to the detection and/or measurement of complementary nucleotide sequences, and have not as yet achieved the widespread usage or commercial importance of antibody-based assay methodologies.

The binding reaction between high concentrations of analyte and antibody may be observed 'directly' in consequence, for example, of the formation of a visible precipitate (comprising the analyte-antibody complex), whose amount is indicative of the amount of analyte in the test sample (assuming a sufficiency of antibody to be present). This approach formed the basis of traditional methods used to quantify both antigens and antibodies, such as the immuno double-diffusion and immunoelectrophoresis techniques. However, for greater sensitivity, either of the reactants may be labeled using a marker more readily detectable than the reactants or reaction products themselves, enabling observation of binding reactions between lower reactant concentrations. One of the original labels used for this purpose comprised red cells, to whose surface antigen was linked. The presence of antibodies in a test sample was detected by cell agglutination (arising from cross-linkage by the antibody), resulting in a characteristic layer of agglutinated cells at the bottom of the incubation tube or well. This technique was also used to detect specific antigens in test samples by their inhibitory (competitive) effect on the agglutination reaction between antibody and (identical) antigen on the red cell surface. Such techniques were semiquantitative in that they yielded a somewhat imprecise measure of the maximal dilution of test samples causing visible agglutination.

The emergence of far more precise and sensitive immunoassays followed the adoption of radioisotopic labeling techniques for the observation of antibody-antigen reactions. The original methods of this genre relied on the use of labeled antigens (used essentially as tracers of unlabeled antigen present in test samples), and are now commonly known as radioimmunoassays (RIAs). The term is occasionally applied to methods relying on isotopically-labeled antibodies; however, the term immunoradiometric assay (IRMA) is conventionally applied to methods based on the latter approach.

Immunoassays characteristically display high structural specificity, reflecting the ability of appropriately selected antibodies to distinguish and bind

to antigenic sites (epitopes) on particular analyte molecules. The use of high specific activity isotopes such as ^{125}I or ^3H (or, in the case of DNA probes, ^{32}P) to label either the antibody or (tracer) analyte permits binding reactions between small numbers of molecules to be readily monitored, endowing these methods with exceedingly high sensitivity. These attributes, coupled with their relative simplicity, underlie the widespread use of isotopically-based immunoassays in medicine and biology and increasingly in many other related fields (e.g. the food industry, agriculture, forensic science, environmental monitoring, etc.). Since the early 1980s, however, increasing interest has focused on so-called alternative, nonisotopic techniques based on principles identical to those of RIA and IRMA, albeit differing in the reagent labels used. Various environmental, legal, economic and practical considerations underlie this development (e.g. the limited shelf-life of isotopically-labeled reagents, the problems of radioactive waste disposal, the complexity of radioisotope counting equipment, the demand for diagnostic kits for home use, etc.), most of which are primarily of social or logistic significance. Other factors are more fundamental, relating to the development of methodologies of greater sensitivity than the isotopic methods or which address other analytical objectives unattainable using isotopic labels. Such objectives include the development of transducer-based immunosensors for directly measuring analyte concentrations in biological fluids, and multianalyte assay systems capable of measuring multiple analytes in the same sample.

A wide range of nonisotopic labels have been employed in this context, of which the most commonly used are enzymes, and chemiluminescent and fluorescent substances. Regrettably, the diversity of different labels now in use has given rise to a confusing range of acronyms by which the differing assay formats developed by individual researchers or immunoassay kit manufacturers are known. The conventional terminology distinguishing the original, isotopically based methods is often used; for example, methods relying on fluorescent labels are referred to either as fluoroimmunoassay (labeled antigen) or immunofluorometric assay (labeled antibody), on enzyme labels as enzymeimmunoassay and immunoenzymometric assay, etc. However, other terms – some of which depart from this convention – are also in common use, including, for example, enzyme-linked immunosorbant assay (ELISA; generally signifying the use of an enzyme labeled antibody and solid-phase antigen), time-resolved fluoroimmunoassay (TR-FIA; based on time-resolution methods of fluorescence measure-

ment), and competitive enzyme-linked immunoassay (CELIA; relying on the use of enzyme-labeled antibodies in a competitive assay mode).

The terms 'competitive' and 'noncompetitive' frequently feature in descriptions of immunoassay and other binding assay methodologies, as exemplified by CELIA and competitive protein-binding assay (CPBA). These terms (and similar descriptions, such as 'inhibition' assay) derive from the historical portrayal of certain binding assay methods (e.g. RIA) as dependent on competition between unlabeled and radiolabeled (tracer) analyte for a limited number of antibody (or protein) binding sites. For this reason, labeled antibody methods are frequently viewed as inherently noncompetitive, the terms being used virtually synonymously. However, certain labeled antibody methods are also described as competitive (e.g. CELIA), evidently on the grounds that, as with labeled analyte methods, maximal sensitivity is achieved using restricted amounts of antibody (see below).

The underlying reasons for the existence of these two broad types of assay may be clarified by brief consideration of the basic principles governing immunoassay. All such assays essentially rely on the measurement of (fractional) antibody binding site occupancy by analyte following reaction between the two. However, binding site occupancy may be determined either by *direct* measurement of *occupied* sites (noncompetitive assay), or by *indirect* measurement, i.e. by the measurement of *unoccupied* sites, from which binding site occupancy is inferred (competitive assay). The optimal amount or concentration of antibody yielding maximal assay sensitivity largely depends on which of these alternative strategies is adopted, tending to infinity in the first case, and to zero in the second. This difference in assay design – which is essentially unrelated to which component, if any, of the assay system is labeled – underlies the distinction between, and differing performance characteristics of, noncompetitive and competitive methods. For example, introduction of labeled analyte into the assay system either following, or during, the reaction between antibody and analyte provides a method of estimation of unoccupied antibody binding sites, implying that all labeled analyte methods may be classed as competitive. In contrast, if labeled antibodies are employed, the assay may be classed as competitive or noncompetitive, depending on the approach used to separate and measure binding sites occupied by analyte. Thus, if an immunosorbant is used to sequester unoccupied sites, and labeled antibody *attached to the immunosorbant* is determined, the assay is competitive. Conversely, if labeled antibody *remaining in solution* (i.e. antibody bound to analyte) is measured, the assay

is noncompetitive. Assuming an efficient method of separation of occupied from unoccupied sites, the optimal antibody concentrations yielding maximal sensitivity will significantly differ, depending on which of these alternative approaches is adopted.

Irrespective of whether (tracer) analyte or antibody is labeled (but assuming the use of a label of infinite specific activity), the maximal sensitivity attainable using a competitive assay may be shown to be ϵ/K , where ϵ represents the experimental error (cv) in the measurement of the assay response variable (e.g. fraction of labeled analyte bound to antibody), and K = the antibody affinity constant *vis-à-vis* analyte. For example, if experimental errors in the measurement of the assay response approximate 1% (i.e. $\epsilon = 0.01$), and $K = 10^{12} \text{ l mol}^{-1}$, the maximal sensitivity attainable using a competitive approach is about $10^{-14} \text{ mol l}^{-1}$, i.e. about 6×10^6 molecules ml^{-1} . The use of radioisotopic labels (such as the iodine isotope ^{125}I) of finite, albeit high, specific activity, does not, in practice, significantly reduce assay sensitivity (assuming use of an antibody of affinity constant about $10^{12} \text{ l mol}^{-1}$ or less). This implies that no significant sensitivity improvement can result from the substitution of other labels in immunoassays of competitive design. However, in the case of noncompetitive immunoassays, similar theoretical analysis reveals that (assuming efficient separation of occupied from unoccupied labeled antibody binding sites), sensitivities of about 10^2 – 10^3 molecules ml^{-1} are, in principle, attainable, albeit only using labels of much higher specific activity than the commonly used radioisotopes. These conclusions underlie the current development of a variety of ultrasensitive, noncompetitive, labeled antibody methods relying on, for example, lanthanide chelate fluorophors, chemiluminescent substances such as the acridinium esters, and various enzyme labels.

A disadvantage of the use of high antibody concentrations in noncompetitive assay designs is a concomitant loss in assay specificity, arising from the increased relative potency of substances other than the analyte as the antibody concentration is raised. (Note that all substances capable of reaction with an antibody become equipotent in an immunoassay when the amount of antibody is infinite.) This problem is minimized in so-called 'sandwich', or 'two-site' assays, relying on dual antibodies. The first, linked to a solid support – often termed the 'capture' antibody – is generally directed against one epitope characterizing the analyte molecule and is used to isolate molecules bearing the epitope from the medium. The second (labeled) antibody, directed against a second epitope, enables determination of the number of captured analyte molecules adhering

to the solid support which carry *both* epitopes. Sandwich assays thus combine the sensitivity of the non-competitive approach with the specificity improvement inherent in dual-epitope recognition, and – subsequent to the development of *in vitro* techniques of monoclonal antibody production – have emerged as the dominant methodology for the assay of analytes of large molecular size. (Note, however, that isoforms of many analytes (e.g. erythropoietin) differ in both structure and biological activity, notwithstanding their possible possession of many identical epitopes. Thus, sandwich immunoassays cannot be assumed to be totally specific for analyte molecules of a single, unique, structure, and may therefore be analytically invalid. This phenomenon contributes to the problems of immunoassay standardization.)

For the two-site dual antibody approach to be successful, the analyte molecule must be of sufficient size to permit its simultaneous binding to two different antibodies without steric impediment. Attempts to develop sandwich assays for analytes of small molecular size (such as steroid hormones) by generating antibodies reacting exclusively with occupied capture-antibody binding sites have so far failed, largely because of the propensity of antibodies generated against occupied sites also to bind to unoccupied sites. However, a recently described technique relies on blocking of unoccupied sites by an anti-idiotypic antibody prior to exposure of capture antibody–analyte complexes to labeled antibody. The latter – prohibited from binding to unoccupied sites – thus binds only to capture antibody–analyte complexes. The technique thus constitutes a noncompetitive assay for analytes of small molecular size, and is thus potentially capable of yielding greater sensitivity. However, it remains questionable whether the approach provides the specificity advantages of a genuine sandwich assay, and overcomes the loss in specificity that the use of large amounts of labeled antibody to maximize sensitivity implies.

A further reason for the adoption of nonisotopic labels is the necessity, in the case of the isotopically-based methods, for physical separation of the immunological reaction products, whichever is labeled. Certain nonisotopic labels permit the reaction products to be distinguished without such separation, methods based on their use being generally described as homogeneous. In practice, such methods have in the past been largely confined in their application to analytes of small molecular size, relying on a labeled form of the analyte, the signal from which is affected by its binding to antibody. Certain commercial assay kits rely on the use of enzyme labels, whose activity is either restricted or enhanced when the labeled analyte is antibody bound. Another tech-

nique relies on fluorescent labels, and exploits alterations in the plane of polarization of the fluorescent emissions when the labeled antigen molecule is in free or antibody-bound states. Such techniques are of relatively low sensitivity, and their use has been confined to the assay of analytes present in biological fluids at relatively high concentration, such as therapeutic drugs. Recently, however, homogeneous sandwich methods of high sensitivity for the assay of analytes of large molecular size have been developed by various manufacturers and are beginning to appear on the immunodiagnostic market. One such method relies on a time-resolved fluorescence detection system involving the transfer of laser excitation energy from one antibody (labeled with a fluorescent europium cryptate) to the second, the latter (labeled with the fluorophor allophycocyanine) forming the complementary part of the sandwich. Such energy transfer essentially only occurs when both antibodies are simultaneously bound to individual analyte molecules and are therefore in close proximity. Thus only analyte molecules simultaneously bound to the two antibodies generate a detectable signal.

Neither analyte nor antibody is labeled in a conventional sense in the case of the newer immuno-sensor technologies now under development. Such devices comprise a solid probe on whose surface antibody is coated; antibody occupancy following exposure to an analyte-containing medium is monitored by an internal transduction system, yielding an observable electronic or optical signal. A number of such transduction systems, such as field-effect transistors (FETs), have been proposed, but most have proved either too low in sensitivity or vulnerable to nonspecific effects to be of practical use. A promising contender in this field relies on surface plasmon resonance (SPR), an electronic effect generated in an ultrathin conducting metal (e.g. gold or silver) film on glass (or quartz) when light impinging at a particular angle on the glass–air interface is internally reflected. The resonance angle depends on the mass of material present at the interface; it thus alters in response to changes in the occupancy of antibody (or antigen) molecules coated to the metalized/glass surface. Instruments relying on these principles are now commercially available, albeit they are primarily intended for research studies (such as epitope mapping) rather than for routine immunoassay use. Although likely to prove of great value in certain situations, the transducer-based sensor approach to antibody-occupancy measurement possesses a number of potential drawbacks which makes it uncertain that it will substantially replace conventional label-based methodologies in the near future. For example, the specificity improvements offered by two-site

sandwich assays (particularly in the context of high-sensitivity, noncompetitive assay designs) makes large-scale reversion to single-site immunoassays unlikely. Although sensor techniques such as SPR are capable of detecting second (i.e. sandwich-forming) antibodies bound to analyte molecules adhering (via capture antibody) to a glass surface (particularly if the second antibodies are labeled with, for example, colloid metal particles to increase their mass), the inclusion of second antibodies in an assay system narrows the distinction between sensor-based and conventional label-based methods of antibody-occupancy measurement. Thus the future impact of SPR and other transducer-based techniques is likely to depend largely on the reduction in operational costs, if any, that they offer as compared with current methodologies. Meanwhile, the slow rates of association and dissociation of antigen-antibody complexes imply that the ultimate goal of immunosensor development – the ability to monitor changing analyte concentrations in a medium – remains far from fulfillment.

Another development – that of multianalyte immunoassay systems – reflects an increasing need to measure many different analytes in the same sample, both in medicine and in many biologically-related fields, e.g. the food industry. The possibility of developing such technologies also emerges as a consequence of the availability of very high specific activity, nonisotopic, reagent labels, e.g. fluorescent labels. This permits the development of high sensitivity 'microspot' immunoassays in which a capture antibody is located on the surface of a probe within an area no more than 50–100 μm^2 . This in turn permits construction of multimicrospot arrays, each microspot directed against a different analyte. Provided the total number of capture antibodies located within each microspot is 'small' (i.e. about 0.05 ν/K or less, where ν = the volume of the analyte-containing medium to which the microspot is exposed), fractional occupancy of capture antibody binding sites is solely dependent on the analyte concentration in the medium. Moreover, by labeling both capture antibody and a second 'recognition' antibody (directed against either occupied or unoccupied sites) with different labels, e.g. two fluorescent labels, the analyte concentration can be derived by observation of the ratio of signals emitted from the microspot when exposed, for example, to laser illumination. Thus, by utilization of laser scanning techniques comparable to those employed in other fields, arrays of many different antibody microspots may be rapidly examined, thus permitting the development of simple multianalyte immunoassay methodologies capable of

measurement of many different analytes in the same small biological sample.

Microarray techniques of this kind (but relying on oligonucleotide arrays rather than antibody arrays) are also applicable to DNA analysis; such development constitutes the objective of the US Genosensor Project, established in 1992.

Antibody microspot arrays may be constructed on a commercial scale using, for example, ink-jet spotting techniques. Researchers at Boehringer Mannheim GmbH have described the use of this approach to construct arrays comprising 196 microspots located on the flat circular base (3 mm in diameter) of a plastic sample container, these being produced at a rate of approximately 5000 chips an hour. A somewhat different approach has been adopted by the Californian company, Affymetrix Inc., for the construction of oligonucleotide arrays for use in DNA analysis. This relies on the use of so-called combinatorial chemical techniques to construct (*in situ*) the different oligonucleotide sequences within the individual spots that make up the oligonucleotide array. The technique involves sequential masking and exposure of selected areas on a silicon base using photolithographic techniques similar to those used in the electronics industry for the construction of semiconductor chips. Such technology – although applicable to binding agents such as oligonucleotides and polypeptides which can be built up sequentially – are obviously not applicable to antibodies, which cannot be synthesized in this fashion.

The current intense interest in microarray technologies being displayed both in Europe and in the USA, and in the development of both manufacturing techniques and appropriate instrumentation, suggests that antibody microspot arrays will form the basis of the next major revolution in the field of immunoassay. But whether or not this prediction is fulfilled, binding assay methodology of one form or another is clearly likely to retain a dominant position in the microanalytical armamentarium for the foreseeable future. *In vitro* techniques of monoclonal antibody production have removed much of the element of chance associated with *in vivo* antibody production methods, and increased control over the nature, properties, and long-term availability of binding reagents. The recent introduction of single domain antibodies (dAbs) by Ward and colleagues, which rely on genetic engineering techniques for the *in vitro* production of the heavy chain variable (V_{H1}) domain of selected antibody molecules, represents a further step along a path leading ultimately to the synthesis of entirely artificial analyte-recognition binding molecules.

IMMUNOCONGLUTININS

Peter J Lachmann, Coombs Building, Centre for Veterinary Science, Cambridge, UK

Bovine serum normally contains a protein known as 'conglutinin', which is responsible for the tight aggregation ('conglutination') of complement-coated erythrocytes. Conglutinin is not convincingly found in the serum of species other than Bovidae but a similar activity can be generated in other species, either by immunizing them with complement-coated material or spontaneously after *in vivo* complement activation. These factors are called the immunoconglutinins and are autoantibodies to neoantigens exposed in fixed complement components but not in free complement components. C3 and C4 are the major complement components that become fixed at complement fixation sites and most immunoconglutinins react with hidden determinants in bound C3 and C4. Although neoantigens are known to occur in the membrane attack complex, autoantibodies to these neoantigens following *in vivo* complement activation have not so far been described.

Although immunoconglutinins of all immunoglobulin classes can be detected, those that are measured by the usual agglutination techniques are predominantly immunoglobulin M (IgM) and they are the equivalent for the complement system of the 'rheumatoid factors' which react with bound immuno-

globulins. Human sera all contain low levels of immunoconglutinin but elevated levels are diagnostic of *in vivo* complement activation and thus are found in acute and chronic infections and in chronic inflammatory diseases. They are particularly high in intravascular infections which give rise to high IgM antibody formation (e.g. African trypanosomiasis), but high levels are also encountered in chronic bacterial infections and in chronic viral infections. In minimal change nephritic syndrome, raised immunoconglutinin titers are the only evidence that complement activation is involved. Immunoconglutinins have a fairly limited role in diagnostic immunopathology, most recent publications being concerned with their levels in parasitic infections.

A special example of immunoconglutinins are the so-called nephritic factors which are autoantibodies to the alternative (but very rarely the classical) pathway C3-convertases. These antibodies stabilize the C3 convertases and thereby derange complement homeostasis.

Nephritic factor (Nef) is concentrated in the IgG3 subclass and is larger than the usual IgG molecule by virtue of increased glycosylation. The stimulus for forming Nef is unknown, but it is more commonly found in subjects carrying the C3F allele. Subjects

with Nef have low plasma C3 levels. Nef was first described by Spitzer and colleagues in 1969 in patients with mesangiocapillary glomerulonephritis, but there is a stronger association with partial lipodystrophy. A few subjects with Nef have systemic lupus erythematosus (SLE) and occasionally there is no associated disease.

IMMUNOCYTOCHEMISTRY AND ENZYME MARKERS

CD Mackenzie, Environmental Pathobiology Laboratory, Department of Pathology, Michigan State University, East Lansing, Michigan, USA

Immunocytochemistry (ICC) involves the visual identification of target molecules in tissues and cells through the specific interaction of antibody(s) with antigen by using antibodies labeled with indicator molecules. The antibody is tagged with a specific signal generator (indicator), e.g. a fluorochrome, color-producing enzyme or metallic particle. The sensitivity, or strength of the signal, can be enhanced by increasing the indicator/antigen ratio; this is done through a variety of indicator-amplifying mechanisms.

The essential requirements of ICC are: a) production of sensitive and specific antibodies to a selected antigen and marker reagents, b) optimal treatment of tissues in terms of fixation and histopreparation to promote optimal interaction between target molecules and reagents, and c) appropriate identification (quantification) of the indicator molecule, all with optimal tissue preservation. ICC reagents can nonspecifically stain the tissues in a similar fashion to that of standard histochemical stains, thus appropriate controls are essential.

ICC is essentially simple in concept, however there is a considerable degree of technical knowledge and expertise needed to adequately perform the assay, and it can be difficult to interpret. Many different approaches and marker systems now exist and the overall sensitivity of ICC has been much improved in recent years. This has been due in no small part to an increase in the specificity of antibodies used, brought about by monoclonal antibody (mAb) technology, as well the development of more refined tissue fixation for use in ICC, automated approaches that standardize procedures, as well as more sensitive quantitation systems.

The first labeling of antibodies was achieved by John Marrack in 1934. This was taken up by the major pioneer of immunocytochemistry, Albert Coons, who with advice from Creech and Jones used isothiocyanate methodology to couple a fluorescent label to rabbit antisera directed against pneumococci. Other names that deserve mention in developing ICC include Kunz, who in 1941 began working towards a new way of localizing tissue constituents, Nakane who introduced enzymes to produce colored reaction products as markers, as well as Sternberger and Mason who independently developed methods for amplifying enzyme systems. In recent years there have been advances in the chemistry of fluorochromes and in development of sensitive systems to assess and quantify these useful labels.

ICC systems

ICC methods can be divided into four groups:

The direct method (see Figure 1) Here a labeled antibody (known as the primary antibody) attaches directly to the target antigen in the tissues. An inherent problem with this system is that unwanted antibodies directed against tissue antigens are also labeled and can attach to the tissue section thus producing high backgrounds. The use of mAbs can reduce this contamination.

Indirect methods Here the marker molecules are attached to a secondary antibody applied to recognize the presence of a primary antibody on the target antigen. Indirect methods enhance stain strength and

Figure 1 The basic forms of immunocytochemical reactions.

use less reagent but problems still exist with regard to the need to block unwanted couplings.

Bridge indirect methods The bridge principle involves an antibody lying between the primary antibody and the antibody carrying the indicator molecule. A number of variations on this technique exist, including some that involve the use of enzyme-antibody complexes. Commonly used examples are peroxidase-antiperoxidase (PAP) and alkaline phosphatase-antialkaline-phosphatase (APAAP) complexes. All bridge procedures can be intensified by repetition of the staining sequences thus producing a 'branching' effect.

Double staining methods These are used to identify more than one antigen in a single tissue section. In this approach the first immunoreagent and its marker is fully developed, then a prolonged rinse in an acid buffer removes this first antibody leaving only the reaction product behind, and finally the second reaction proceeds superimposed on top of the first. A problem with double staining lies in the fact that the marker antibody used for the first antigen may still have sites available for the second antibody, and this results in an unclear color reaction produced by the intermingling of the two colors.

Antibodies

Most of the antibodies used in ICC to date are immunoglobulin G (IgG), with a minority being IgM. The species of animal used for the production of antibodies should be genetically as far removed as possible from that of the test reagent. Two major concerns are the sensitivity and the specificity of the antibodies used. As a general rule, an increase in one of these is usually associated with a reduction in the other. The specificity of ICC lies largely with the antibody.

The strength (or avidity) of the binding between antigen and antibody is important in ICC. Antibodies should be of high avidity, as low-avidity antibodies will become detached during washing or may themselves block the attachment of the preferred high-avidity antibody. Repeated incubations in anti-serum will increase the chances of high-avidity antibodies refilling any epitopes freed of low-avidity molecules during the washing steps, thus resulting in increased detection efficiency and improved sensitivity. This also allows for the use of more diluted antibodies and thus a reduction in cost. The extent of dilution used for ICC assays is also important as it is possible to dilute out contaminating antibodies, as well as interfering proteins and enzymes.

Nonspecificity can be due to heterogeneous antibody reagents and to shared amino acid sequences (i.e. antigen cross-reactivity). A remedy for this problem is purification of the antibody reagent. However this often causes a reduction in the important highly avid antibody forms. Other techniques adopted include the use of high dilutions of antibodies, absorption by 'common' tissue preparations (e.g. liver powder), staining first with nonimmune serum from the same species as the primary antibody was derived. The carrier proteins (such as serum albumin) used in the preparation of antihapten antibodies for ICC are sometimes impure and can lead to cross-reactivity.

The size of the antibody (and its attached marker molecules) affects its ability to penetrate into tissues and reach the target antigens. One approach taken is to use fragments of antibodies, such as Fab fragments, where penetration into the tissues is a critical factor, e.g. with pre-embedding staining.

The preparation of antibodies is therefore a primary concern in ICC and the removal of contaminating antibodies is a major requirement. Purification of polyclonal antibodies by standard immunochemical techniques often is inadequate for ICC. Affinity purification, it must be remembered, works well for antibodies of low or medium avidity but not

for those of high avidity (i.e. the type needed for ICC).

A technique useful for isolating mAbs from polyclonal sera involves blot affinity purification. Here a nitrocellulose filter containing antigen is treated as one would a tissue, i.e. vapor fixed, incubated with polysera, washed and eluted to produce antisera free of nonspecific reactions. Techniques that specifically purify the IgG out of immune sera should only be employed if it is necessary to remove other serum components or enzymes. In fact, crude serum may be as good as, or even better, than purified reagents in many instances.

The testing of an antibody for ICC is best carried out using a known positive tissue. This will not only determine the background but also the avidity, and show that the antibody will resist the washing process. In general terms other techniques are inferior, although the ELISA assay is closer in relevance to ICC than radioimmunoassay (RIA). Cytochemical paper (nitrocellulose) dot blots and artificial tissue sections are useful where filter paper is treated as for tissue sections (e.g. vapor fixed, embedded and sectioned) and tested for different levels of antigens.

The size and complexity of the antigen to which the antibody is directed influences the effectiveness of the reagent. Antibodies directed against certain areas of a molecule are advantageous; however the smaller the area the more the chance of cross-reaction with other molecules. Thus, in peptide immunocytochemistry it is often essential to stain sections with antibodies to several different regions of the molecule, e.g. the N-terminal, the mid-portion and the C-terminal amino acid sequences. Consequently, it is often useful to use a cocktail preparation of monoclonals.

Monoclonal antibodies have now been developed that are more functional in ICC and which identify embedding and fixation resistant epitopes, e.g. those which recognize CD45 (leukocyte common antigen). Anti-idiotypic antibodies have been used for cytochemical identification of peptide receptors in the CNS.

The localization of indicator molecules in tissues by using technique systems based on chemistry other than antigen-antibody interactions is fruitful in some circumstances. The *Staphylococcus aureus* component protein A links specifically to the Fc portion of IgG and can be labeled with standard ICC markers. The avidin-biotin linking system is popular. Avidin, which can be linked directly to indicator enzymes, is a large glycoprotein (mol. wt 68 000) and has four binding sites for the low molecular weight (mol. wt 242) vitamin, biotin; probing antibodies are linked to biotin (biotinylated). Antibodies directed against

the biotin label on biotinylated entities are now used to replace the biotin-avidin link.

A problem accompanies the use of biotin as a marker molecule due to the presence of natural levels of this vitamin in the tissues. Thus alternatives such as the steroid hapten digoxigenin (DIG) has been developed as a marker system because it is absent from animal tissues and cells; DIG occurs in plants of the *digitalis* family.

Antigens

The tissue component detected by ICC is an antigen, or a complex of antigens, located in a structurally and biochemically complex microenvironment. The conditions needed for successful ICC include an insoluble antigen that remains *in situ* and preservation of the tissue architecture to allow adequate morphological identification.

Fixation immobilizes the antigen and preserves the tissue architecture; however this process can reduce antigenicity and interfere with the passage of reagents to the sites of the tissue entities. Thus fixation is one of the most important considerations in ICC and is responsible for many of the comparative discrepancies and limitations of the technique as a whole. Antigens can be extracted by the fixative and lost in some instances. This can be influenced by the antigen's locality (e.g. extracellular spaces extract quickly), and the antigen's inherent properties (e.g. those lacking primary amino and sulfhydryl groups are extracted by aldehyde fixatives).

Two basic forms of fixation are used in ICC: precipitating and cross-linking fixatives. Precipitating fixatives remove lipid but do provide comparatively good penetration by removing the lipid component of membranes. Such fixatives (e.g. ethanol, methanol and acetone) act by precipitating large protein molecules and were commonly used in the early days of immunocytochemistry; the protein denaturation they cause is largely reversible. They are not suitable for electron microscopy as they cause tissue shrinkage and extraction of too many antigens. Nevertheless they may be useful for certain specific purposes (e.g. immunoglobulin localization). However, precipitating fixatives extract rather than fix low molecular peptides.

The cross-linking aldehyde fixatives are the backbone of modern tissue preparation. Formalin and glutaraldehyde are the basic cross-linking fixatives; these are useful for preserving low molecular weight antigens, such as peptides, but less valuable for larger protein antigens, such as cytofilaments and IgGs (where it is better to use the precipitating fixatives). Chemical cross-linkers disturb antigenicity in four

ways: changing the conformation and thus masking epitopes, chemically modifying the reactive amino acids of the epitope, causing steric hindrance, and promoting extraction of the antigens during the washing steps or the embedding procedures. Cross-linkers may also produce artificial barriers within cells to reagents by fixing membranes and cytosolic proteins.

Formaldehyde fixation is not well understood as far as its effect on antigenicity. However, formalin is used widely (particularly in pathology) and is regarded as a relatively mild fixative. Paraformaldehyde (PF), as a source of fresh formaldehyde, has been commonly used in recent years for ICC, particularly in combined fixative solutions. Formaldehyde-amine fixatives have proved useful for ICC. In order for formaldehyde to cross-link proteins it must first react with a primary amino group on one of the proteins. If an exogenous primary amine is present then formaldehyde can cross-link proteins that lack primary amine groups. It has been found that better structural preservation is achieved with an amine formaldehyde combination. Cyclohexylamine-formaldehyde has been used successfully for both electron microscopy (EM) and light microscopy.

It should be noted that washing of formaldehyde- and paraformaldehyde-fixed tissues can lead to the reversal of lost antigenicity and this is especially useful for treatment of pathologic material; washing overnight under running tap water produces satisfactory results for retrospective studies. More recent approaches have involved 'antigen retrieval procedures' which use high temperatures (usually through microwave heating) to re-expose antigens.

Glutaraldehyde is a very effective cross-linker and produces much more permanent states than does formaldehyde; it is also a preserver of enzyme activities working through as yet unknown mechanisms. It penetrates tissues more slowly than formalin and therefore smaller tissue samples must be used.

The use of combination fixatives is now commonplace in immunocytochemistry. This approach was first taken by Karnovsky who perfused organs etc. with a mixture of glutaraldehyde and paraformaldehyde followed by brief immersion of tissues in the fixative at 4°C: the formalin penetrates quickly and protects some of the reactive elements from the more severe effects of the glutaraldehyde. The 'reversible' nature of formalin fixation insures that sufficient sites remain available to react with glutaraldehyde. This combination is suitable for small diffusible antigens; however, some antigens do not suit aldehyde fixation and in these cases it is recommended that parabenzoquinone (PBQ) be used with glutaraldehyde or with paraformaldehyde. Success has also

been achieved with picric acid used with either glutaraldehyde or formaldehyde.

Penetration by a fixative may be slow and this can be overcome or addressed by using small blocks, using vapor fixation of freeze-dried tissue blocks, or by perfusion. A method used successfully for ICC by many is to make cryostat sections of snap-frozen unfixed tissues and then thaw them in the fixative.

Freeze-drying provides optimal enzyme preservation by turning ice into vapor without liquefying the water – the liquid phase of water causes distortion. Rapid freezing produces small ice crystals and minimizes diffusion processes as well as avoiding crystal growth. Freeze-drying and vapor fixational gaseous paraformaldehyde or PBQ is a highly sensitive approach for immunohistological localization of antigens.

Tissue sectioning

The preparation of tissue sections that are both suitable for sufficient entry of ICC reagents and retain the morphology for microscopy requires careful consideration. Paraffin-embedding techniques have caused problems but with improved reagents this has lessened. Nevertheless, cryostat sectioning remains an important approach, although it is necessary to protect the tissues against freezing damage. Cryoprotectants commonly used include dimethyl sulfoxide (DMSO), glycerol and sucrose, with sucrose causing the least blocking of antigenicity. The disadvantages of cryostat preparations include morphological deterioration, diffusion of cellular antigens and the problems of storage and repeated sectioning inconvenience.

Preparation of tissues for EM immunocytochemistry is carried out through three different sequences: 1) No embedding: fixing, freezing, sectioning, and reacting. 2) Pre-embedding: fixing, slicing, reacting, embedding, and sectioning. 3) Postembedding: fixing, embedding, sectioning, reacting. The postembedding technique was given a major boost through the development of colloidal gold linked to protein A. Various sizes of immunogold particle are now available to allow double or even triple labeling.

Permeabilization

It is necessary in most instances to increase the ability of reagents to enter tissues and reach the target sites. In general, cross-linking fixation is preferred to precipitating fixatives but this approach sometimes requires 'unmasking' of antigens. Most commonly used reagents are proteolytic enzymes such as pro-

tease, trypsin, pepsin and pronase. Penetration of reagents can also be achieved by rapid freezing and thawing, which microfractures cells allowing antibody penetration without substantial morphological compromise. Detergents solubilize the membrane lipids but with a lack of predictability of these effects. Cryostat sections themselves have improved antibody penetration since the action of freezing and thawing opens the cells. Membrane permeabilizing agents include sodium deoxycholate, digitonin, saponin and Triton X-100. Saponin is the most useful for EM where the membranes contain cholesterol. As described above microwave heating enhances antigenicity.

The stronger the cross-linking fixative in the primary fixation, the less the tissues and cells are permeable to antibodies. One can use Fab fragment reagents and small conjugates in these cases; in contrast, colloidal gold conjugates are often too large and have poor penetration. Postembedding techniques pose no problem with regards to penetration except where epon resins are used and then etching systems must be employed; polar resins get around some of these problems.

Paraffin embedding may damage through many of its steps such as the decalcification step, the heat treatment in wax melting, the effects of the hydrophobic properties of xylene and paraffin which can be detrimental to the proteins and other antigens under question. This preparative procedure is theoretically far from ideal but due to the universality of the technique antibodies that detect antigens in such material are most useful.

Plastic embedding techniques are of two basic forms, i.e. Aroclor and the polar Lowicryl-LR white. ICC sections require the removal of the plastic, removal of the osmic acid and the unmasking of antigens. Plastic materials are therefore not the first choice in ICC although LR white is successfully used for immunogold labeling. Non-embedding approaches for EM ICC have centered around ultracyromicrotomy of lightly fixed or unfixed tissues or cells that are cryoprotected by the infusion with sucrose and are snap frozen. Pre-embedding methods are the choice for cell surface antigen and receptor immunolocalization and the detection of antigens prone to masking by preparative reagents.

Indicator molecules

The earliest labels developed were the fluorochromes, followed by the use of enzymes that produce colored reactions, the first being horseradish peroxidase (HRP). Simple enzyme labels are generally less sensitive than fluorochromes but they have

Table 1 Examples of fluorochrome and enzyme markers used in immunocytochemistry

Propidium iodide

the advantage of being able to be observed at leisure under ordinary bright-field microscopy, and now can in very many cases utilize paraffin-embedded tissues. The enzymes commonly used include HRP, glucose oxidase or intestinal alkaline phosphatase (Table 1). Immunoenzyme techniques allow a wide range of colors ranging from the red of amine ethyl carbazole as a chromogen for HRP, the black reaction product for Fast Blue RR used with alkaline phosphatase, to the blue or purple of the formazan reaction product formed by glucose oxidase. Immunoenzyme techniques can be improved in sensitivity through bridging techniques in which relatively large numbers of indicator molecules (enzyme) are incorporated. Penetration of the comparatively large enzyme labeled antibodies into tissues and cells can be a problem. In the early days enzyme antibodies only reached two or three cells deep into the tissues, but this became less of a problem when the membrane permeabilizing agents were introduced in the late 1970s.

An example of the usefulness of enzyme ICC is the fact that in biology today enzymes are often localized by their immunocytochemical reactivity rather than by biochemical reactions.

Peroxidase is most commonly used to produce permanent brown stain, which can also be developed as either red, blue or even green, with different substrates. Endogenous peroxidase can be a problem and this must be blocked by treatments with agents such as hydrogen peroxide and methanol, periodide and borohydride, sodium nitroferricyanide or phenylhydrazine. Enzyme complex methods such as PAP are 100 times more sensitive than the enzyme used alone; since the peroxidase molecules are immunologically bound and not chemically bound, and their enzyme activity is not compromised.

As the diamino-benzidine used to develop the brown peroxidase product is carcinogenic it is important to consider using alternatives such as:

- Haker-Yates reagent (paraphenylenediamine-pyrocatechol) to produce a blue/black end product;
- 4-chloro-1-naphthol method giving a dark blue purple reaction product; or
- 3-amino-9-ethylcarbazol (AEC) method which produces a red product. This is usually counterstained with hematoxylin.

Sternberger combined peroxidase with antiperoxidase to form a stable cyclic complex with three peroxidase molecules to two antibody molecules (Figure 1). Some examples of immunoperoxidase staining are shown in Figure 2.

Alkaline phosphatase is being used increasingly as a label, despite the fact that many mammalian tissues contain these enzymes. The commonly used substrate is naphthol-AS-phosphate or Fast Blue BB. The problem of endogenous alkaline phosphatase may be resolved by the use of specific fixatives, or inhibitors such as levamisole, and with 20% acetic acid. Alkaline phosphatase-anti-alkaline phosphatase complexes (APAAP) are useful in cases where there is a problem with using PAP because of endogenous peroxidase, e.g., erythrocytes and eosinophils.

Glucose oxidase (GO) is an under-utilized enzyme marker system. Its strength lies in that this enzyme is absent from mammalian tissues, being a bacterial enzyme (from *Aspergillus niger*), and in that it is four times larger than HRP with many more amino groups, and therefore in theory it can generate a larger reduction product. The presence of the GO label is demonstrated by the oxidation of its substrate (i.e. glucose) and the reduction of a tetrazolium salt to form a colored deposit, a formazan. Nitro blue tetrazolium is commonly used in this reaction because of its rapid and strong reaction as well as the fact that its formazan permits precise localization as its blue color contrasts well with peroxidase brown. Glucose oxidase has been used in avidin-biotin immunoglucose oxidase system and with a glucose oxidase-anti-glucose oxidase technique.

Metallomarkers are popular for EM localization of antigens but are also now increasingly common in light microscopy. Gold as a second-level antibody label is also useful and can be built up in a complexed manner thus strengthening the response. Gold particles can be made to any size and have become the standard marker for EM immunocytochemistry. Gold labeling can be greatly enhanced by silver enhancement systems.

Colloidal gold is useful for light microscopy where gold particles backscatter light under dark field optics; this approach is useful for paraffin sections; epipolarization optics are best used for observing cell

suspensions. The indirect immunogold silver staining method for the detection of leukocyte and other cell surface antigens in cell smears involves the use of bright-field microscopy and counterstaining with

May–Grunwald–Giemsa stain; this reveals gold as black granules on the surface membrane of the cells. Alternatively, epipolarization microscopy reveals bright granules on the dark background and the

increase in contrast compared with bright-field microscopy makes this a more sensitive approach.

Gold linked to immunoglobulins, toxins, antigens or protein A have all been used for staining of EM sections on grids (i.e. postembedding procedures).

Immunogold for light microscopy usually uses a more concentrated primary antibody solution than used with the PAP method. It is probably less sensi-

tive than DAB, but is reliable and gives a good color contrast by producing a red-colored gold reaction.

The availability of 1 nm gold particles now permits the use of a particulate label with standard pre-embedding EM techniques for the first time. These small particles must be enlarged, however, for transmission electron microscopy.

Nonspecific binding of colloidal gold in cytochemical reactions can usually be prevented by the addition of macromolecules such as protein solutions (BSA, ovalbumin, gelatin and milk proteins) as quenching agents. It is believed that electrostatic charges are the basis of the nonspecific binding properties of colloid gold complexes.

Controls

It is essential with such a sensitive and variable technique as ICC that a high standard of controls must be maintained. Various levels and types of controls can be used:

Method controls

1. A known positive tissue.
2. A test tissue stained with nonimmune primary layer, inappropriate antiserum, and no primary antisera (these should all be negative).

Antiserum specificity controls

1. Antibody preabsorbed with the specific antigen.
2. Antibody preabsorbed with inappropriate antigen.
3. Antibody absorbed with antigen fragments or structurally related antigen. This approach gives information on epitope specificity.

Much care must be taken in the use of controls both in carrying out those that are appropriate, and in their interpretation. First-level controls indicate the specificity and validity of the primary antibody-antigen reaction. Second-level controls relate to the tissue quality as well as the staining quality (e.g. the presence of endogenous marker interference such as enzyme or autofluorescence). These must be negative before one can make any valid assessment of the tissues in terms of a specific ICC reaction.

False-positive adsorption controls can be caused by the presence of immune complexes which may bind to, for example, Fc receptors. If binding sites for the antigen in question still remain in the tissues then the complexes may bind to these. False observations may arise because there may be enzymes in the antisera that destroy the antigen and there may be contamination of the antibodies.

Interpretation

The sensitivity of the immunocytochemical method is not evaluated by staining intensity, rather it is measured by the ratio of specific staining intensity to the amount of background staining intensity. It is important to differentiate between the type of staining in a cell and not simply whether it is positive or negative. The morphology of staining also is important: a truly positive reaction is generally heterogeneous in distribution either within a cell, amongst a group of cells or throughout a tumor; diffuse monotonal staining is in all likelihood nonspecific. For example, with lymphocytes the uptake of antigens is seen as diffuse cytoplasmic staining, usually most marked at the periphery of cells and has a smooth pattern. Synthesis of the target antigen by the cells will show a more intense staining around the nucleus and less at the periphery of the cell and it will appear as a granular pattern. A conservative approach to interpretation of results from lightly fixed or unfixed tissues is prudent.

Other labeling systems

Radio-immunocytochemistry (RICH), where the marker molecule is a radiolabel detected through autoradiography is generally too slow a procedure and is not commonly used although it is still used for *in situ* hybridization.

Optical systems

The optical system utilized for immunocytochemistry should be of sufficient quality to allow the clear distinction between a positive stain and the negative background. The use of differential interference contrast optics (DIC or Nomarski) is highly suitable for immunocytochemistry. These optics are particularly helpful in visualizing the fine deposits of immunoperoxidase. Fluorescence ICC requires more expensive microscopic equipment.

Current uses for ICC

The *in situ* visualization of antigens in tissues and individual cells has been a major addition to the technical armamentarium of pathologists, immunologists, histologists and anatomists (especially neuro-anatomists), plant biologists and more recently molecular biologists.

Immune markers have been used to investigate leukemias, tissue neoplasms (for example, antikeratin staining for thymomas and epithelioma) and the localization of peptide hormones in tumors. Carcino-

embryonic antigen (CEA) is used for colonic adenocarcinomas and an epithelium membrane antigen (EMA) is used for breast carcinomas, as are estrogen receptors.

In recent years immunocytochemistry has become an important addition to diagnostic cytology, however the indications for ICC are not at present as broad in this area as they are for histopathology. As the available cell markers increase in number the use of ICC for cytology will also increase. A primary need is an ICC marker that defines a difference between benign and malignant cells; a combination of immunocytochemistry and DNA hybridization technology may provide this first.

Quantitation

Most of the information generated with immunocytochemistry involves some form of quantitative statement. Although these are usually highly subjective judgements there is a need for more quantitative information. Theoretically three forms of information can be derived: 1) number of immunopositive elements in a defined area; 2) the amount of staining present; and 3) the amount of antigen present in a defined compartment. Microfluorimetry and microdensitometry have been attempted. Problems that can arise with quantifying antigen in tissues result from: 1) the difficulty in preserving all of the epitopes; 2) the inadequate penetration into the tissues of the antibodies used in the detecting agents; 3) steric hindrance reducing the efficiency of the detection procedures. It must be remembered it is only the top of a section that is stained; this affects quantitation. New laser-equipped fluorescence analysis systems which generally use argon ion lasers can analyze with remarkable accuracy the emissions from proteins antibody labeled with fluorescein isothiocyanate (FITC) and R-phycoerythrin. These newer techniques suggest that highly accurate quantification can be achieved with immunocytochemistry, and this area of immunology may be quickly transformed into a truly quantitative system.

In situ hybridization techniques

Immunocytochemistry does not provide detailed information about expression of a protein since rapid secretion or intracellular degradation may cause negative immunocytochemical results despite high levels of protein synthesis; *in situ* nucleic acid hybridization corrects some of these problems. The combination of *in situ* hybridization and immunocytochemistry permits further insights into the mechanisms of regulation of gene expression at the single

cell level and should find application in both research and in diagnostic histopathology.

IMMUNODEFICIENCY, ANIMAL MODELS OF

Gregory J Bancroft, Infectious and Tropical Diseases, London School of Hygiene and Tropical Medicine, London, UK

The effects of mutations at specific genetic loci give considerable insight into many areas of biology. This is particularly true for the genetically determined syndromes of human immunodeficiency which can cause partial to severe impairment of immune function, often with a lethal outcome. While important information has come from analyzing tissues from these patients, animal models of immunodeficiency are crucial for understanding how genetic abnormalities affect immune competence. Studies on the laboratory mouse have provided much of our knowledge on the normal function of the immune system, so it is not surprising that this species also provides the most widely used animal models of immunodeficiency. This system allows for the production of large numbers of genetically identical animals bearing distinct defects in immune responsiveness.

In the past, most of these models came from spontaneously occurring mutations. Fewer examples derive from selected breeding of an outbred stock to obtain alterations in particular immune responses. The most well studied of these are the Biozzi lines originally selected for high and low antibody responses to sheep erythrocytes, and lines selected for high- versus low-affinity antibodies to protein antigens. Other examples of altered immune competence occur in strains such as the NZB, which has severe autoimmune and immunodeficiency characteristics. However, such systems based on polygenic differ-

ences from normal inbred mouse strains are difficult to study due to the magnitude of the genetic changes involved. On the other hand, spontaneous mutations can generate immune abnormalities due to single mutant genes which are generally easier to identify and backcross on to other genetic backgrounds. These offer the greatest opportunity of identifying the gene or gene product involved and the possible identification of homologous loci in humans.

Among the hundreds of known mouse mutants, many affect immune competence. In some, the primary manifestation is in the immune system, but the majority involve changes in other organs which were the basis for their original isolation (e.g. coat color). Only two (*nu* affecting the thymus and *Dh* affecting the spleen) actually result in the absence of a lymphoid organ. The remainder are the result of intrinsic stem cell abnormalities (e.g. *scid*) or of defects in essential growth factors (e.g. *Sl* or *op*). Alternatively, defects in particular cell functions can cause abnormal responses to certain stimuli (e.g. *lps*), while others can be secondary to hormonal alterations in the animal (e.g. *ob*). Finally, deficiency in the complement components C5 and C4 can occur in some mouse strains due to genes encoded on chromosome 2 (*Hc*) and 17 respectively.

This entry will briefly review the genetically determined animal models of immunodeficiency. More detailed descriptions of these and other mutants can be found in the Further reading listed

below. Details of the athymic nude mutant and immunodeficiency associated with autoimmune diseases will be discussed elsewhere. It is important to note that, apart from the inherited defects presented here, immunodeficiency can be acquired by infection of the host with a variety of microorganisms. This can extend to responses against heterologous antigens as well as those of the infecting organism and is seen particularly in infection with the parasitic protozoa such as *Trypanosoma cruzi* and *Plasmodium* as well as of course in the context of human immunodeficiency virus (HIV) infection and acquired immune deficiency syndrome (AIDS). Indeed, there is growing interest in generating models of AIDS by infection of experimental animals with various retroviruses. Retroviruses of both the onco- and lentivirus subfamilies can induce immunodeficiency syndromes in mice (e.g. MAIDS), cats (feline leukemia virus), chickens (avian leukosis virus) and monkeys (simian immunodeficiency virus). Furthermore, some murine models of immunodeficiency are being adapted to develop systems for modeling HIV infection *in vivo* (e.g. SCID-hu chimeras) and to study the opportunistic infections which ultimately are responsible for mortality in these patients. Finally, two important advances have occurred over the last few years. Firstly, with the increased application of molecular methods, many of the naturally occurring mutations in mice which affect immune competence have been localized to a specific gene. Structure-function studies of the proteins they encode have now been performed and, in some cases, human homologs of these genes and their defects have been found. Secondly, there has been a revolution in the development of novel, immunodeficient mice by the use of transgenic and in particular 'knockout' technology. These techniques have radically altered our approaches to the generation and use of immunodeficient animal models and hold the key to developing ever more useful and clinically relevant models of human disease.

Primary defects in immune competence

Severe combined immune deficiency

Mice homozygous for the autosomal recessive mutation 'severe combined immune deficiency' (*scid*) are the result of a random mutation occurring in the CB-17Icr strain. This was first identified by the absence of serum immunoglobulins in affected animals and maps close to the mahagenoid locus and centromeric to the immunoglobulin λ light chain locus on chromosome 16. Adenosine deaminase (ADA) levels are unaffected by the mutation (the gene encoding ADA is on chromosome 2) and *scid*

mice share some characteristics with human SCID patients with normal ADA. Further analysis of this mutant showed that both T and B lymphocyte lineages were functionally deficient in *scid* mice. In addition to hypogammaglobulinemia, *scid* mice do not mount humoral immune responses to either T cell-dependent or independent antigens *in vivo* and are unable to reject histoincompatible skin grafts. In culture, spleen or lymph node cells from *scid* mice do not proliferate in response to T or B cell mitogens and do not develop proliferating or cytotoxic T cells during one-way mixed lymphocyte reactions.

The absence of functional responses from both T and B cell compartments is reflected in the lymphoid organs *per se*. T cell development is arrested at a point equivalent to 14–15 days of gestational age, with 98% of thymocytes being CD4⁺/CD8⁺ (compared to only 2% in immunocompetent CB-17 controls), lacking CD3 and expressing low levels of CD2. In the spleen, a few Thy-1⁺ cells are present but again CD4- or CD8-bearing cells are virtually absent. Development of the B cell lineage is arrested at the pro-B cell stage prior to the expression of cytoplasmic or surface immunoglobulin. However, while pre-B cells bearing cytoplasmic μ chain are undetectable *in vivo*, they can be generated from *scid* bone marrow *in vitro*, albeit at a reduced frequency. Interestingly, natural killer (NK) cell differentiation does occur in *scid* mice, with normal numbers of both bone marrow progenitors and functional cytotoxic cells in the periphery. The latter express the NK cell makers NK2.1 and ASGM1 but not T cell subset markers such as CD4/CD8, again suggesting that NK cell development is independent of mature T cell differentiation. NK cells in *scid* mice provide an alternate (i.e. non-T cell) source of interferon γ (IFN γ) which can mediate macrophage activation and partial resistance to infection with intracellular pathogens such as *Listeria monocytogenes* and *Toxoplasma gondii*. This natural resistance pathway may help to explain why, despite the loss of T and B cell function, *scid* mice can usually be maintained under pathogen-free conditions for over a year.

The abrogation of cellular development in *scid* mice is restricted to cells of the lymphocytic series. Myeloid and erythroid lineages are apparently unaffected by the mutation and mast cell progenitors are present in the bone marrow of homozygotes. In contrast, *scid* mice do not develop increased mast cell numbers *in vivo* following challenge with *Nippostronglyus*, presumably due to a defect in cytokine production as a result of their T cell deficiency. Normal numbers of macrophages are found in the peritoneal cavity, spleen and liver which produce interleukin 1 (IL-1) and tumor necrosis factor α

(TNF α) *in vitro* and can be activated for tumoricidal activity and enhanced expression of class II histocompatibility molecules when incubated with cytokines such as IFN γ . The normal expression of class II histocompatibility antigens in *scid* tissues differentiates this defect from a subset of human SCID patients where deficiency of a DNA binding protein for the X box HLA class II promoter region abrogates expression of these molecules.

The *scid* mutation arrests the development of T and B lymphocytes while maintaining the normal stroma and environment of the lymphoid organs. Bone marrow stem cells from *scid* mice are unable to restore lymphoid function in lethally irradiated normal CB-17 recipients, but, conversely, CB-17 stem cells can reconstitute the lymphoid defect in the *scid* mouse. The *scid* defect therefore results in an intrinsic abnormality in lymphoid stem cells. The molecular hallmark of the *scid* mouse is the absence of lymphocytes bearing antigen-specific receptors. Abnormal T cell receptor or immunoglobulin gene rearrangements are observed in transformed lymphoid cells, spontaneous thymomas or long-term bone marrow cultures derived from *scid* mice. The joining of appropriate coding regions is either undetectable or occurs with massive deletions involving V(D)J gene segments. This suggests that *scid* mice have an active but defective system for the recombination of antigen-specific receptor genes. The inability to express a productively rearranged receptor would presumably be lethal for developing cells, accounting for the selective arrest in lymphocyte development. However, if this process is bypassed by transgenic introduction of already rearranged T cell receptor or immunoglobulin (Ig) genes, mature T and B cells can now be detected, although in the case of the B cell compartment their expression in peripheral lymphoid tissue is still reduced. Recently, the molecular basis of the SCID mutation has been identified as a deficiency in activity of a DNA-dependent protein kinase (DNA-pk). This is a member of the PI3 kinase family which serves in V-D-J recombination and double stranded DNA break repair. It is currently believed that SCID cells have a nonsense mutation in the catalytic subunit of this enzyme, resulting in normal protein expression but impaired function. However, this defect may not account for the increased radiosensitivity of human autosomal SCID cells which can express normal DNA-pk activity.

Motheaten

Mice homozygous for the 'motheaten' (*me*) and 'viable motheaten' (*me^v*) genes have proved difficult to study due to their short lifespan (3–6 weeks). Both strains usually die from pneumonitis characterized

by infiltration with macrophages, neutrophils and lymphocytes. However, the earliest features of the mutation are observed in the skin, where aggregates of neutrophils result in the characteristic motheaten appearance. The skin is also involved later when there is a reduction in the number of major histocompatibility complex (MHC) class II⁺ Langerhans cells. Although the extent of immunodeficiency shows some minor differences between *me* and *me^v* strains, motheaten mice in general show severely reduced responses to T cell-dependent and -independent antigens, T and B cell mitogens as well as impaired levels of cytotoxic T cell and NK cell activity. Thus, unlike *scid* mice, affected animals have loss of B, T and also NK cell function and represent one of the most severe animal immunodeficiency models.

A prominent histological feature of this mutant is the involution of the thymus and depletion of cortical thymocytes at approximately 4 weeks of age. Cell transfer studies show that prothymocytes are present in normal numbers in the bone marrow of *me^v* mice but are unable to migrate to the thymus and have impaired chemotactic responses to thymic culture supernatants *in vitro*. In contrast to atrophy of the thymus, splenomegaly occurs due to a shift in hematopoiesis from the bone marrow to the spleen. This is mediated by an increase in myelo- and erythropoietic activity at the expense of normal lymphoid development with depletion of the periarteriolar T cell areas.

Although B cell numbers are reduced in the spleen, those remaining are abnormally enriched for cells of the Ly-1 phenotype. This lineage is associated with the production of autoantibodies (such as in the NZB strain) and represents only a minor fraction of B cells in the normal host. In contrast, greater than 50% of hybridomas derived from *me^v* spleen cell show autoreactivity to self antigens on thymocytes, erythrocytes and skin, consistent with the immune pathology observed in the mutation. Motheaten mice also exhibit hypergammaglobulinemia with a skewed B cell repertoire and raised circulating levels of B cell maturation promoting cytokines.

Motheaten mice show profound changes in bone marrow function and do not produce lymphocytes under Whitlock–Witte culture conditions, nor stem cells or neutrophils under Dexter culture conditions. In fact, adherent stromal cells from motheaten mice actively inhibit normal bone marrow cultures by direct cell contact, suggesting that the *me^v* defect is primarily due to alterations in the lymphoid/myeloid microenvironment. However, this has recently been contradicted by the finding that aberrant lymphoid development can occur in normal mice given *me^v*

bone marrow, suggesting an additional intrinsic T and B cell defect.

Molecular examination of cells from motheaten mice has helped to explain this complex phenotype and identified the absence of the tyrosine phosphatase SHP-1 (previously known as PTP-1c, SHPTP1 or HCP) as the primary defect in this mutant. SHP-1 is a key negative regulator of tyrosine phosphorylation events which drive receptor-mediated signaling in many immune cells, including macrophages and lymphocytes. Cells from motheaten mice have a frameshift mutation in SHP-1 resulting in a null phenotype associated with uncontrolled tyrosine phosphorylation and activation of key signaling molecules, including the CSF-1 receptor in macrophages and the src family kinases lck and fyn in T cells. As a consequence, motheaten T cells show a defect in apoptosis which may underlie the pneumonitis observed in these mice which includes actively cycling T cells. However, the multiple tissue pathologies seen in these mice is not solely due to a T and B cell-mediated autoimmunity, as previously suggested. Breeding of the motheaten strain on to the RAG-1 background deletes all antigen-specific lymphocytes but does not abrogate the inflammatory lesions, splenomegaly and elevated hematopoiesis which characterizes the motheaten mutant *in vivo*.

X-Linked immunodeficiency

Genes localized to the X chromosome are essential to the development of the immune system, and in humans at least six immunodeficiency syndromes have been mapped to this chromosome. In mice, the most established X-linked abnormality is seen in the CBA/N strain which bears a recessive mutation at the *xid* gene. This results in abnormal B cell development seen in homozygous female or hemizygous male mice. CBA/N mice have a reduced number of B cells and lack a mature population of Lyb-3⁺5⁺7⁺ cells expressing sIgM^{lo}/sIgD^{hi} and peritoneal Ly-1⁺ B cells. As a result, serum levels of IgM and IgG3 antibodies are reduced, and, most characteristically, CBA/N mice are unable to respond to Ti-2 antigens such as pneumococcal polysaccharide. CBA/N B cells can be activated *in vitro* with soluble, mitogenic preparations of anti-Ig antibodies to enlarge and increase expression of MHC class II antigens, but will not proliferate. Furthermore, these cells do not respond appropriately to IL-5, IL-10, lipopolysaccharide (LPS) and cross-linking of either CD38 or CD40. Long-term cultures of CBA/N bone marrow show normal numbers of myeloid and B cell lineage colonies, which show enhanced kinetics of development. Contrary to earlier hopes, the residual B cells present

in CBA/N mice may not be analogous to the immature B cells seen during normal neonatal development. B cell development is unusually T cell dependent as a result of the *xid* mutation and few B cells are found in athymic *nu/nu-xid* double congenics, giving a phenotype much more akin to human X-linked agammaglobulinemia.

In addition to affecting humoral immune competence, the CBA/N defect may also have more subtle effects on other cell types. Macrophage and NK cell-mediated cytotoxicity are normal, but altered T cell and accessory cell functions have been described. CBA/N mice exhibit several functional consequences as a result of their humoral immunodeficiency. Affected animals have low levels of naturally occurring tumor-specific antibodies and show enhanced susceptibility to inoculation with transplantable tumors. They are also more susceptible to infection with organisms such as *Salmonella typhimurium*, *Plasmodium* and *Giardia*.

The *xid* locus was originally linked to at least one of the XLR (X-linked, lymphocyte-regulated) sequence family which encode RNA transcripts expressed only in T and B lymphocytes. Evidence that changes in intracellular signaling account for the B cell abnormalities observed in affected mice began with the finding that CBA/N cells have reduced inositol phospholipid metabolism and Ca²⁺ mobilization following triggering with anti-Ig. CBA/N B cells also differ in the expression of glycoproteins noncovalently linked to surface IgM and IgD. Together with the finding that these cells respond normally to agonists which act further down the signaling cascade (such as calcium ionophore and phorbol esters), the functional B cell defect in CBA/N mice was suggested to act at a relatively early process in B cell membrane signaling. This has been borne out by the demonstration that *xid* mice exhibit a point mutation in Bruton's tyrosine kinase (Btk), a member of the Btk/Tec family of nonreceptor tyrosine kinases. The *xid* mutation occurs in the pleckstrin homology (PH) domain of the enzyme which is likely to mediate the interaction of Btk with other signaling molecules such as PI3, PIP2 and protein kinase C. Mutations in Btk form the structural basis for the human XLA phenotype but these can also occur at other sites in the molecule such as in the kinase domain *per se*.

Another mutation at the X chromosome, *scurfy* (*sf*), results in dermatological and hematological abnormalities as well as X-linked immunoproliferative disease. The *scurfy* locus occurs in an X chromosome segment which is homologous to the human chromosome region encoding the gene for the Wiskott-Aldrich syndrome protein (WASP) and is inseparable from the murine WASP locus by backcross

analysis. Wiskott–Aldrich syndrome is the result of a mutation in human WASP, a proline-rich protein involved in regulation of the actin cytoskeleton and possibly also tyrosine kinase-dependent cell signaling events. Together, the *scurfy* and *xid* mutants share some phenotypic features with this syndrome which is characterized by impaired responses to polysaccharide antigens along with eczema and platelet abnormalities.

Responsiveness to bacterial lipopolysaccharide

Lipopolysaccharide (LPS) derived from the outer membrane of gram-negative bacteria has profound effects on mammalian inflammatory and immune responses. This is primarily mediated by the lipid-A component which has pleiotropic actions ranging from initiation of fever and endotoxic shock to the activation of host macrophages, lymphocytes and fibroblasts. Mutation at the *lipopolysaccharide response* (*Lps*) locus on chromosome 4 has occurred independently in C3H/HeJ and C57BL/10ScN mice, resulting in impaired immunological responses to LPS. Thus, C3H/HeJ (*lps*^d) mice have increased resistance to endotoxin shock induced by administration of LPS *in vivo*, correlating with the impaired generation of inflammatory cytokines such as IL-1, IL-6 and TNF α . Based on these results, one would predict increased resistance of nonresponder mice to the lethal effects of infection with gram-negative bacteria. In contrast however, C3H/HeJ mice have greater susceptibility to infection with *Escherichia coli* and *Salmonella* and can be protected from lethal infection by exogenous administration of purified TNF α and IL-1. Thus, early production of these cytokines is critical for host resistance and activation of macrophages for microbicidal activity.

Numerous studies have also demonstrated the effect of this mutation *in vitro*, with particular emphasis on the impaired mitogenic responses by C3H/HeJ B cells. Macrophages from these mice also have multiple defects in LPS-mediated responses, including induction of tumoricidal and microbicidal activities. Unresponsiveness is specific for LPS, in that C3H/HeJ macrophages respond normally to other stimuli such as the combination of phorbol myristate acetate and calcium ionophore or gram-positive bacteria. C3H/HeJ mice have a higher incidence of mammary tumors and increased susceptibility of their macrophages to virus infection *in vitro* due to impaired endogenous interferon production. Recently, the structural gene cluster for IFN α (*Ifa*), which was also mapped to chromosome 4, has been segregated from the *Lps* locus using recombinant inbred mice. This suggests a causal link between impaired LPS responsiveness and interferon pro-

duction rather than the presence of the *lps* gene as part of the *Ifa* gene cluster.

While the functional effects of the *Lps* gene have been extensively documented, the biochemical basis for the defect is still unclear. Studies with radiolabeled LPS demonstrate equivalent binding to cells of both LPS responder and nonresponder mice, and normal expression of the 80 kDa LPS binding receptor, suggesting a deficit in signal transduction (rather than ligand binding) in the *lps* mutant. This is supported by observations that, unlike normal cells, C3H/HeJ macrophages do not undergo intracellular translocation of protein kinase C from the cytoplasm to the actin cytoskeleton following interaction with LPS. In addition, LPS is also unable to induce extracellular signal regulated kinase (ERK2) activity in nonresponder macrophages, and thus triggering of the ras/MAPK signaling pathway for cell activation does not occur. Finally, it is important to note that mice bearing the *lps*^d allele can respond to LPS derived from some rough strain mutants of *Salmonella* and *E. coli* and also lipid-A-associated proteins. The presence of the latter depends upon the method of LPS purification and may account for responses of C3H/HeJ mice to some LPS preparations.

Immunodeficiency with defects in other organ systems

Among the large number of mutations affecting coat color in the mouse, several have been found to alter immune competence. The most extensively studied of these are a series of mutations at the 'beige' (*bg*) locus on chromosome 13. A primary histological feature of *bg/bg* mice is the presence of abnormal lysosomal granules in several cell types and lack of elastase and cathepsin D. This is associated with defective vesicular transport and fusion between lysosomes and late endosomes. This mutation is considered a model of the Chediak–Higashi syndrome in humans which shares the enzyme and lysosomal granule abnormalities and is predisposed to lethal pyogenic infection. Indeed, a candidate gene for the beige mutant (*Lyst*) has been identified on mouse chromosome 13, which has a closely related human homolog on the syntenic region of human chromosome 1q. *Lyst* has been found to contain a frameshift mutation in a child affected with Chediak–Higashi syndrome, whereas a 5 kb deletion within the gene is observed in the beige mutant mouse.

The beige mutation provided the first experimental model of impaired NK cell function. NK cells are present in normal numbers in *bg/bg* mice but are unable to kill susceptible tumor target cells due to a defect in the postrecognition process of target lysis.

These mice have decreased resistance to a variety of infections and transplantable tumors and are frequently used to determine the importance of NK cells in host resistance. Unfortunately, while initial studies described this mutation to be selective for NK cells, more recent work has identified abnormalities in a variety of other immune parameters including development of cytotoxic T cells, macrophage tumoricidal activity and neutrophil chemotaxis and microbicidal function. Furthermore, the production of IFN γ by NK cells in these mice is reportedly normal. Thus, the *bg* mutation offers a model for the study of NK cell cytotoxic (but not secretory) activity, but the other changes in immune function must be considered before ascribing resistance solely to NK cells.

Two other independent mutations also affecting both lysosomal function and NK cell activity have been described, 'Pale ear' (*ep*) mice can halt the progression but are unable to eradicate infection with *Leishmania donovani*, the causative agent of visceral leishmaniasis, and show defective granulomatous responses in infected tissues. 'Pallid' (*pa*) mice spontaneously develop emphysema and have an inherited deficiency in serum α_1 -antitrypsin and defective lysosomal secretion.

Mutation at the 'agouti' locus (*A*) on chromosome 2 also determines coat color and these mice show enhanced susceptibility to neoplasia, along with reduced humoral and phagocytic functions. These defects correlate with the degree of obesity and raised blood insulin levels in mice heterozygous for the dominant alleles *A^y* and *A^{vy}*.

Mutations at the 'dominant white spotting' (*W*; chromosome 5) and 'Steel' (*Sl*; chromosome 10) loci have multiple effects, including anemia and defects in gametogenesis and pigmentation, but are particularly useful in analysis of mast cell development. Homozygotes or mice bearing compound alleles (e.g. *W/W^v* or *Sl/Sl^d*) have less than 1% of the normal number of tissue mast cells. Passive cutaneous anaphylaxis reactions are absent in *W/W^v* mice but they retain systemic anaphylactic responses, possibly via basophil degranulation. The expulsion of intestinal parasites can be normal or delayed depending on the organism studied. Humoral immune responses are unaffected, but evidence for the predicted effects of mast cell depletion on development of delayed-type hypersensitivity responses is contradictory. Cell transfer studies and the growth of mast cell precursors *in vitro* have suggested two distinct mast cell defects in these strains. *W/W^v* mice lack stem cells which can proliferate and differentiate into mast cell colonies in response to fibroblast-derived growth factors. Similar results have also been described for the mast cell-deficient *mi/mi* mutation (see below). In

contrast, mast cell progenitors are present in *Sl* mutants but connective tissue cell monolayers from the latter are unable to support their development *in vitro*. The *W* locus is now known to encode the receptor tyrosine kinase c-kit, whereas the *Sl* locus encodes its ligand Steel factor (c-kit ligand or mast cell growth factor). In normal mast cells, binding of Steel factor results in autophosphorylation of the c-kit receptor, allowing its subsequent interactions with PI3 kinase and phospholipase C γ 1, two essential mediators of intracellular signal transduction. However, in the *W* mutant this phosphorylation does not occur, preventing engagement of downstream signaling pathways and appropriate cell activation. Mutant mice also display an increased sensitivity to lethal doses of ionizing radiation which may be related to the apoptosis suppressing properties of Steel factor *in vitro*. Interestingly, Steel factor is induced in the gut following challenge with *Salmonella* or cholera toxin whereas *W* mutant mice have increased susceptibility to oral salmonellosis, suggesting that this ligand-receptor interaction is also involved in local protective mechanisms against infection in the intestinal tract.

Immunodeficiency also occurs with genetic abnormalities in other organ systems. These include mutations affecting neurological, skeletal and endocrine development. Mice homozygous for the recessive mutation 'wasted' (*wst*) on chromosome 2 show progressive vacuolar degeneration of neural tissue leading to paralysis and death. This is associated with pronounced immunological changes, include thymic atrophy and reduced numbers of B cells and IgA at mucosal sites. These mice also express altered levels of endogenous cytokines, transforming growth factor β 1 (TGF β 1), IFN γ and IL-2, compared with controls. Presence of the *wst* allele has been correlated with enhanced expression of endogenous murine leukemia virus RNA. However, it is unclear whether this represents a causal or secondary effect of the immune deficit. Also of interest is the abnormally high incidence of chromosomal damage and poor DNA repair seen in lymphoid tissue of *wst/wst* mice. Studies on the *wst* mutation may thus help understanding of the triad of immunodeficiency, neuropathology and abnormalities of DNA repair also characteristic of the human disease ataxia telangiectasia. T cells from these mice exhibit high spontaneous and radiation-induced apoptosis. Other recessive mutations affecting both immune and neurological function include 'lethargic' (*lh*) on chromosome 2 and 'motor end-plate disease' (*med*) on chromosome 15.

Autosomal recessive mutations affecting bone resorption can also impair immune function. Mice

homozygous for the 'gray-lethal' (*gl*), 'oseopetrosis' (*op*), 'osteosclerosis' (*oc*) and 'microphthalmia' (*mi*) mutations (the last also affecting pigmentation and eye size) show alterations in osteoclast numbers or morphology and a range of immune deficits affecting both humoral and cellular responses. Mice homozygous for the *op* mutation also have reduced numbers of macrophages and are unable to synthesize macrophage colony-stimulating factor (M-CSF). Both the osteoclast and macrophage deficit can be partially restored by administration of exogenous M-CSF, suggesting that absence of this growth factor is the primary defect in these mice.

Finally, several mutations causing obesity and noninsulin-dependent diabetes in mice have been examined for immune responsiveness. In particular, the 'diabetes' (*db*) and 'obese' (*ob*) mutants have been demonstrated to have impaired cell-mediated immune responses *in vivo*, possibly associated with increased corticosteroid levels. These deficits are not manifest when lymphoid cells are tested *in vitro*, suggesting a reversible abnormality associated with metabolic changes *in vivo*.

Models of immunodeficiency in other species

In comparison to the murine system, relatively few models of genetically determined immunodeficiency exist in other species. The autosomal recessive *nude* gene has been identified in laboratory rats, resulting in loss of both thymic development and hair. This gene has been backcrossed on to several genetic backgrounds and nude rats have many uses in parallel to studies in athymic mice. Also, the BB rat is an experimental model for insulin-dependent diabetes and one of the sublines from this strain (BB-DP) has a profound reduction in T lymphocytes. These animals have reduced numbers of both CD4 and CD8 lymphocyte subsets and the absence of T cells bearing the RT6 marker. Transfer of BB-DP bone marrow to irradiated normal recipients does not result in development of RT6 positive cells, suggesting an intrinsic defect in T cell development. Consequently, BB-DP lymphoid cells show abnormally low proliferative and cytotoxic T cell responses. The latter may also be explained by subnormal levels of CD8 antigens present on the residual antigen receptor bearing T cells in these animals.

A model of severe combined immunodeficiency (SCID) also occurs in Arabian horses as an autosomal recessive trait. Death due to secondary infection usually occurs within 6 months of age and affected animals show increased susceptibility to opportunistic pathogens such as *Pneumocystis* and

Cryptosporidium. This defect is characterized by lymphoid hypoplasia, hypogammaglobulinemia and the absence of functional T and B cells. Some prothymocytes and phenotypically mature thymocytes can be detected in the thymic remnant, but cortical thymocytes are almost absent. Large granular lymphocytes can be detected in the peripheral blood and develop NK-like cytotoxic activity following incubation with IL-2. Finally, X-linked SCID has also been reported in dogs and is associated with a four base pair deletion in the IL-2 receptor γ gene. Thus these animals share some phenotypic and functional characteristics with the murine and human SCID defects.

Maintenance and use of immunodeficient animals

While some of the immunodeficient mouse strains described above are kept under normal housing conditions, those with severe abnormalities (e.g. *scid*) are frequently kept in sterile or aseptic environments. This can be achieved by providing autoclaved food, bedding and water and covering the sterilized cages with filter bonnets. Alternatively, sterile air laminar flow racks or flexible film isolators can be used for more stringent control of the environment. Infection of immunodeficient mouse colonies with opportunistic pathogens is a serious problem. Of these, mouse hepatitis virus and *Pneumocystis carinii* are particularly severe. Some protection against *Pneumocystis* can be achieved by prophylactic administration of trimethoprim-sulfamethoxazole but this is microbistatic and not microbicidal and therefore requires continual use.

Variation in the extent of immune deficiency can occur among mice of a particular strain. For instance, T cell function can be readily demonstrated in older athymic nude mice or following infection with experimental pathogens. In the case of *scid* mice, some 15% of offspring derived from homozygous *scid/scid* mating will show some serum immunoglobulins, usually accompanied by partial restoration of T cell function. The frequency of such 'leaky' *scid* mice increases with age and the degree of environmental stimulation (i.e. higher in normal versus specific pathogen-free conditions) and is overcome by routine screening of serum immunoglobulin levels prior to use.

As seen above, several animal immunodeficiency models share characteristics with selected human immunodeficiency syndromes (Table 1). Others have no direct homology to specific human diseases but instead provide valuable insight into the processes controlling normal immune function. In addition to providing information on the basic mechanisms of

Table 1 Common murine models of immunodeficiency

Name	Gene symbol	Chromosome	Primary characteristics	Similar to human
SCID	<i>scid</i>	16	T/B cell deficiency	ADA-positive SCID
Mothaten	<i>me</i>	6	Impaired T/B/NK cell function and hypergammaglobulinemia	
Viable motheaten	<i>me^v</i>			
Nude	<i>nu</i>	11	Absence of thymus	DiGeorge syndrome
Lipopolysaccharide	<i>lps</i>	4	Impaired responses to LPS	
X-linked immunodeficiency	<i>xid</i>	X	Absence of mature B cells; impaired response to T1-2 antigens	Wiskott–Aldrich syndrome
Complement deficient	<i>Hc</i>	2	Absence of C5	
Beige	<i>bg</i>	13	Impaired NK cell function	Chediak–Higashi syndrome
Dominant spotting	<i>W</i>	5	Mast cell deficiency/anemia	
Steel	<i>Sl</i>	10	Mast cell deficiency/anemia	
Wasted	<i>wst</i>	2	Thymic atrophy, abnormal DNA repair	Ataxia telangiectasia

immune development (e.g. the recombinase system in *scid* mice), these models have been used to address many other questions. For instance, animals with selected deficiencies can replace the experimental ablation of particular lymphoid populations in normal animals. Thus the *scid* mutation may provide a more defined model of B cell deficiency than normal mice treated with anti-IgM antibodies from birth.

A common use of immunocompromised animals has been in the analysis of resistance to neoplasia or infection. The original finding that human or murine tumors could be grown in athymic nude mice has provided an enormous literature on the tumorigenicity and metastatic potential of various tumors *in vivo*, as well as models to assess the efficacy of new chemotherapeutic agents. Experimental infection of normal versus immunodeficient animals can identify the pathways of immunity relevant for resistance to particular pathogens. For instance, studies in nude or *scid* mice have demonstrated the role of T cells in development of sterilizing immunity to many facultative or obligate intracellular pathogens such as *Listeria* and *Leishmania*. Immunodeficient animals also allow the study of opportunistic pathogens which do not infect the immunocompetent host. For instance, new models of infection with organisms including *Pneumocystis* (an important AIDS-related pathogen), *Borrelia burgdorferi* (the causative agent of human Lyme disease) and reovirus have been developed in immunodeficient *scid* mice. In view of the life-threatening opportunistic infections seen in AIDS patients and other immunodeficiency states, these may provide models for screening of new therapeutic agents as well as for studying the pathogenesis of infection in the immunocompromised host.

Immunodeficient animals also provide ideal recipi-

ents for *in vivo* reconstitution with different lymphoid or myeloid cell types. These range from the routine *in vivo* passage of hybridomas to more complicated transfers of specific cell populations and their effects on resistance to infection or antigenic challenge. The inability of some immunodeficient animals to reject foreign tissue has been taken to its logical extreme by the passage of human cells into immunodeficient mice. This was originally attempted over a decade ago in athymic mice given grafts of human skin. More recent interest has come from reports of the maintenance and growth of human lymphoid cells in immunodeficient *scid* mice. The presence of viable T lymphocytes in such *scid* hu chimeras has been used to set up experimental models of HIV infection. The similarity of this system to the human disease is still under scrutiny, but is being used to assess the *in vivo* efficacy of anti-HIV drug treatments. Chimeric *scid*-hu mice are also now susceptible to infection with Epstein–Barr virus (EBV) and may provide a unique opportunity to study the mechanisms of EBV-induced lymphoproliferative disease in an experimental animal.

Targeted generation of novel immunodeficiencies

Since the early description of the athymic nude mutation, animal models of immunodeficiency have continued to provide important insights into the immune system. Most have arisen by spontaneous mutations which have then been tested for their effects on immune function. In addition to the new mutants which will undoubtedly be discovered, it is now possible to selectively induce genetic immunodeficiencies *in vivo*. Methods to achieve this fall into

three major groups. The first example is the backcrossing of mouse strains with independent mutations to achieve double (e.g. *nu/xid*) or triple (e.g. *nu/xid/bg*) congenic strains. This can result in either additive effects of each independent characteristic or apparent synergy in which more severe defects are observed. In addition, existing mutants can be treated to delete residual immune responses for specific tasks. Thus the ability of SCID mice to permit growth of human cells *in vivo* can be increased by antibody-mediated depletion of NK cells prior to engraftment.

By far the most important advances have come from molecular manipulation of the mouse genome either by direct transgenesis or gene deletion (knockout) technology. Transgenic insertion of new or modified genes allows removal of specific cell types or neutralization of function of key molecules in the immune system. Thus, the herpes simplex type 1 thymidine kinase gene (HSV-1-tk) can be transgenically introduced in the mouse genome using lymphoid cell specific promoters. Dividing lymphoid cells expressing HSV-1-tk are then selectively ablated in adult mice by administration of nucleoside analogs (such as ganciclovir) which are converted to toxic metabolites by viral but not host thymidine kinase. This procedure has been used to delete T and B cells in lymphoid organs of transgenic mice *in vivo*. Other methods using constitutive transgenic expression of the A chain of ricin or diphtheria toxins are also being examined, but the ability to control when cell ablation occurs by altering the dose and timing of analog delivery has multiple advantages. Alternatively, overexpression of normal genes by transgenesis can result in novel models of immune deficiency. For example, mice expressing a human CD3 ϵ transgene show ablation of both T lymphocytes and NK cells *in vivo*, while overexpression of the human IL-2 receptor γ chain abolishes NK cells and epidermal dendritic cells in homozygous mice. While these methods rely on insertion of functional genes, the alternative approach of overexpressing functionally inactive genes gives rise to 'dominant negative mutants'. This allows selected loss of function mutants where, for example, mice expressing an inactive IFN γ receptor α chain under a macrophage-specific promoter have a functional deficit in interferon responsiveness in this cell type but not others.

However, by far the most powerful models have come from the generation of targeted gene deletion or knockout mice. Here, point mutations, or more usually larger sequences of nonsense DNA (such as the selectable marker conferring resistance to neomycin), are targeted into particular genes in pluripotent mouse embryonic stem cells, thus entering the

germ line. New methods for selecting homologous recombination events rather than simply random insertion of this material (which is the most frequent result of transgenesis) now allows the potential for selective disruption of almost any mouse gene of interest. This approach was first used in the immunological setting to ablate expression of β_2 -microglobulin *in vivo* resulting in loss of CD4 $^+$, CD8 $^+$ T cells. Since the early 1990s the number of genes deleted in this manner has increased dramatically. Improved methods for growth and manipulation of embryonic stem cells *in vitro* and selection of targeted events has meant that this technology is becoming more feasible for many laboratories. Nevertheless, this approach still requires considerable investment in both molecular expertise and animal husbandry to generate founder lines and sufficient stock animals for experimentation. An increasing trend is for new knockout strains to be donated to public repositories, such as the Induced Mutant Resource in the Jackson Laboratories, Bar Harbor, USA, allowing access for investigators who are unable to generate their own animals.

The knockout approach has several distinct advantages over previous methods of studying immune deficiency. Firstly, it is no longer necessary to rely on identification of spontaneously occurring mutants or selective breeding. Secondly, it affords complete ablation of the encoded protein, compared with the risk of incomplete removal of particular cell types or cytokines in antibody-mediated depletion studies *in vivo*. Furthermore, it allows functional deletion of key intracellular proteins (such as kinases or phosphatases involved in lymphocyte activation) which cannot be inhibited by antibodies *in vivo*. Finally, it allows a much more responsive approach to studying the molecular basis of clinical immunodeficiency (Table 2). Thus genes which have been implicated in human syndromes such as p47phox and ZAP-70 (identified as the molecular basis of CGD and a rare form of autosomal SCID, respectively) can be deleted

Table 2 Examples of targeted gene deletions in mice which mimic primary human immunodeficiencies

Deleted murine gene	Human disorder
Bruton's tyrosine kinase	Bruton's X-linked agammaglobulinemia
CD40 ligand	X-linked hyper-IgM syndrome
Janus kinase (JAK-3)	Autosomal recessive SCID
ZAP-70 kinase	
IL-2 receptor γ chain	X-linked SCID
p47 phox	Autosomal recessive CGD
gp91phox	X-linked CGD

from the mouse genome to ask whether this gives the same phenotype as the human disease. This in turn generates a novel animal model for the study of immune development, susceptibility to infection and new therapeutic strategies. Conversely, the phenotype of knockout mice can give new insights into the molecular basis of clinical immunodeficiency. This is illustrated in the contrasting phenotypes following deletion of the IL-2 (normal T cell development) versus IL-2 receptor γ chain genes (resulting in murine SCID) and the identification of the latter as the basis of human X-linked SCID.

Nevertheless, the knockout approach has several inherent disadvantages. Genes which are transcriptionally suppressed or essential for early events in embryogenesis may be difficult to inactivate with this approach. Fortunately, this is less of a problem in studies of the immune system because, if shielded from the risks of infection, most animals with even massive defects in immune competence can mature to adulthood to allow subsequent experimentation. The most commonly cited problem of knockout mice is the issue of compensation. Thus, animals which have developed entirely without a particular component often show overactivity of other immune functions to 'compensate' for this defect, either spontaneously or in response to microbial challenge. In contrast, selective depletion by antibodies in adult mice results in an immediate loss of function and there is usually insufficient time to generate alternative immune pathways. In truth, while compensatory responses may make interpretation of experimental data more difficult, they actually give valuable insights into the plasticity of the immune system which can be relevant to the problems of primary immune deficiencies in humans.

Future perspectives

The study of animal models of human immunodeficiency is undoubtedly in its most exciting phase. The ability to generate genetically targeted deficiencies in

mice has revolutionized this field and provided critical models for other immunologists interested in the molecular basis of normal immune function. One of the most promising new areas is in the generation of inducible knockouts (such as with the recently described Cre-lox system) in which normal development will occur but, at a selected time in ontogeny, the gene of interest can be functionally ablated. Also, transgenic mice expressing specific antisense RNA constructs may allow direct inhibition of a selected gene product in a controlled manner. Finally, as new human genes involved in host immunity are discovered, they can be tested directly for their biological role in transgenic and knockout mouse systems. Hopefully, these new approaches, as well as further investigations of existing mutants, will increase our understanding of normal immune function as well as assist in the development of effective therapies for patients who are afflicted with these defects.

IMMUNODEFICIENCY, PRIMARY

A David B Webster, Department of Clinical Immunology, MRC Immunodeficiency Research Group, Royal Free Hospital School of Medicine, London, UK

The first patient with hypogammaglobulinemia was diagnosed by Bruton in 1952 soon after the introduction of serum protein electrophoresis. At about the same time, severe combined immunodeficiency (SCID) was described in Switzerland and

has subsequently been subclassified into a number of different disorders. In 1965, DiGeorge showed that the thymus was important in humans by describing an athymic infant with recurrent infections.

The term 'primary' is taken to mean that the immunodeficiency is not secondary to any known infection, lymphoreticular malignancy, or drugs. Whilst most 'primary' disorders are due to single gene defects, 'common variable' immunodeficiency and selective immunoglobulin A (IgA) deficiency, which represent the most common disorders, are probably based on a polygenic mechanism. There are also some metabolic disorders where a variety of cell types, including lymphocytes, are affected. In such cases, the distinction between 'primary' and 'secondary' is somewhat arbitrary.

Selective T cell deficiencies

Thymic aplasia

In 1965, DiGeorge described a child without a thymus or parathyroid glands due to congenital malformation of the third and fourth pharyngeal pouch. Most patients have microdeletions at chromosome 22q11, or less frequently at 10p13, where there are probably genes which control the development of the neural crest, from which cells migrate to the pharyngeal pouches. The disorder is familial in a few cases and the prevalence is about 5 per 100 000 children. A spectrum of severity has been recognized, with some children lacking all thymic and parathyroid tissue, sometimes with additional abnormalities in midline structures such as the lips, palate, heart and major thoracic vessels, while others retain some thymic tissue and have mild symptoms. In the severe type, there is a virtual absence of circulating T lymphocytes, sometimes with a relative expansion of B cells. These patients are capable of making antibodies after immunization, although it is unclear whether the quality or quantity of antibodies produced is normal. In general, there is a raised incidence of chronic cytomegalovirus and varicella infection, and some affected children have developed systemic vaccinia infections after immunization. Recurrent bacterial infections are unusual. Autoimmune phenomena, such as hemolytic anemia and vitiligo, may occur.

Early attempts at therapy focused on repleting thymic hormone with fetal thymic grafts, and more recently purified thymic hormone; there is no good evidence that either of these strategies work. Fortunately, most patients have a remnant of thymic tissue left, and the numbers of circulating T cells gradually rise to normal during the first few years of life. There is a possibility that the majority of these lymphocytes are derived from the gut-associated lymphoid tissue.

CD3 defects

Two siblings with autosomal recessive inherited

mutations in the CD3 γ chain gene have been reported, one dying from severe autoimmune disease in infancy, while the other remains healthy at 10 years; this was associated with about 50% of normal expression of the CD3/TCR complex. One child with recurrent lung infections is reported with inherited defects in the CD3 ϵ gene. Since the CD3 ϵ chain is crucial for normal T cell development, the residual 10% of normal expression of the CD3/TCR complex in this patient was presumably enough to provide partial T cell immunity.

Peptide transporter (TAP) defects

A few patients, some apparently not prone to infection, have been reported with very low expression of HLA class I on lymphocytes. This disorder was originally called the 'bare lymphocyte syndrome', but this term should be abandoned because it is sometimes confused with major histocompatibility complex (MHC) class II deficiency (see below). Two siblings with bronchiectasis were recently found to have mutations in the TAP2 gene, causing inefficient transportation of class I to the trans-Golgi compartment. Both had deficient natural killer (NK) cell activity, but no obvious predisposition to viral infection.

Severe combined immunodeficiency (SCID) (Figure 1)

The first cases of SCID were described in Switzerland in the 1950s, hence the original term 'Swiss type agammaglobulinemia', although later it became apparent that cellular immunity was severely compromised. A better understanding of the condition had to await the discovery of T and B lymphocyte markers in the 1970s. Since then the condition has been subclassified, and in most cases the disorder is understood at a molecular level. SCID occurs in about 1:50 000 live births. The syndrome is characterized by severe opportunistic fungal, viral, protozoal and bacterial infections. Affected infants fail to thrive, have chronic diarrhea due to enteric viruses and parasites, have extensive mucosal candidiasis, and develop *Pneumocystis carinii* pneumonia. These clinical features, together with the finding of very low numbers of circulating T cells, negative delayed hypersensitivity skin reactions, poor or absent T lymphocyte transformation *in vitro* with mitogens and thymic dysplasia (without Hassall's corpuscles), is virtually diagnostic. The exceptions are MHC class II deficiency, ZAP-70 defects and Omenn's syndrome, where there are often normal numbers of circulating lymphocytes. Circulating B cell numbers in SCID are variable and sometimes there is polyclonal expansion

Figure 1 Ontogeny of T lymphocytes. The blocks in differentiation/maturation in the primary immunodeficiencies are as follows: A, reticular dysgenesis; B, thymic aplasia/X-linked SCID/PNP deficiency/RAG and JAK3 kinase defects; C, ADA/class II deficiency; D, leaky types of JAK3 and ZAP-70 kinase deficiency; E, some CVID patients, CD3 γ chain defects, and leaky types of CD3 ϵ chain defects.

of one isotype with hyperimmunoglobulinemia. However, functional antibodies are rarely detected. Most affected children die within 1 year of diagnosis unless they receive a successful bone marrow transplant.

X-linked SCID

Affected infants have inherited defects in the common γ chain for interleukin 2 (IL-2), IL-4, IL-7, IL-9 and IL-15 receptors; the defect accounts for about one-third of all SCIDs. Involvement of multiple cytokine receptors explains the severity of this condition.

Adenosine deaminase (ADA) deficiency

The disease was discovered by chance during the routine analysis of erythrocyte isoenzymes in a SCID infant. ADA has a central role in the interconversion pathways of purine metabolism, a defect in the enzyme leading to the accumulation of deoxyadenosine. This accumulates in the plasma and its appearance in the urine is a useful diagnostic marker. Deoxyadenosine is toxic to both T and B lymphocytes, as well as macrophages, which accounts for the very poor prognosis when compared to PNP deficiency (see below). There is a spectrum of clinical severity, probably reflecting different mutations in the ADA gene. Regular subcutaneous injection of calf ADA linked to polyethylene glycol (PEG-ADA) can restore immunocompetence. However bone marrow transplantation provides the only definitive cure. The ADA gene on chromosome 20 has been cloned, and transfection of the gene into bone marrow stem cells or peripheral lymphocytes of patients has been achieved, but so far not enough ADA has been produced to restore immunocompetence.

Purine nucleoside phosphorylase (PNP) deficiency

In 1975, Giblett and colleagues discovered PNP deficiency when screening for purine metabolic defects in patients with T cell deficiencies. The enzyme is important for the interconversion of purines in cells, although its absence only compromises the function of T cells, and in some patients the central nervous system (CNS) and/or neutrophil and erythrocyte development. The substrates for PNP are guanosine and deoxyguanosine, which accumulate in the serum and appear in the urine, the latter being a useful diagnostic marker for the disease. The clinical features are heterogeneous, probably reflecting different mutations in the PNP gene on chromosome 14; some patients present with predominantly CNS features of hypotonia or spasticity, and some have neutropenia or megaloblastic anemia. The numbers of circulating T cells are profoundly depressed (<10%) in severe cases who suffer from the same complications as patients with thymic aplasia. The thymus gland is sometimes atrophic at birth or may gradually atrophy in the first few years of life in those with a delayed onset of the immunodeficiency.

Attempts to block the accumulation of guanosine or deoxyguanosine with purine analogs have been unsuccessful. Bone marrow transplantation remains the treatment of choice in severe cases, although this will not reverse the CNS disease.

JAK3 kinase deficiency

Mutation in this important kinase in the T cell signal transduction pathway is a rare cause of SCID.

Reticular dysgenesis

This is the most severe type of SCID, due to an inherited defect in a pluripotential bone marrow stem cell from which lymphocytes, neutrophils and monocytes are derived. In one reported case there was normal monocyte development. Affected infants only survive a few weeks after birth unless they receive a successful bone marrow transplant.

RAG defects

Mutations in the recombination-activating genes (RAG-1 and -2) account for about a third of T⁻B⁻ SCID, preventing VDJ rearrangement of immunoglobulin and T cell receptor genes.

Defects in NF-AT transcription factor

This rare defect was initially thought to be due to a specific deficiency of IL-2 and was then found to involve NF-AT which controls the transcription of many cytokines.

MHC class II deficiency

This rare autosomal recessive disorder is caused by genetic defects in transcription factors which regulate the MHC class II gene, resulting in failure to express class II on lymphocytes and macrophages; many patients are of North African descent. There is usually a moderate CD4⁺ T cell lymphopenia; lymphocytes proliferate normally *in vitro* with mitogens, but not with specific antigens, and fail to stimulate or respond in a mixed lymphocyte reaction. Molecular defects have been found in three different transcription factors (RFX5, RFXAP and C11TA), and there is a fourth type to be identified.

Omenn's syndrome (familial reticuloendotheliosis)

This unusual form of SCID is characterized by thickened eczematous skin, massive lymphadenopathy, and hepatosplenomegaly due to infiltration of polyclonal lymphocytes, histiocytes, and eosinophils. Circulating B cells may be present at birth, then gradually disappear as the patient becomes severely hypogammaglobulinemic. Until recently many thought that this condition represented a chronic GVH (graft-versus-host) disease due to maternal engraftment of an SCID fetus, but there is now good evidence that it is a distinct disorder.

ZAP-70 defects

A rare genetic cause of SCID involves a tyrosine kinase which interacts with the ζ chains of the CD3 complex, causing a severe functional T cell defect with absence of CD8⁺ cells.

Cellular immune defects and dwarfism

There is a distinct disorder characterized by short limb dwarfism, thin hair and variable T cell deficiency, sometimes with severe hypoplastic anaemia. Relatively common in the Old Order Amesh, over a hundred cases have now been reported in Finland and sporadically elsewhere. SCID occurs in only rare cases. The relevant gene has been localized to chromosome 9p12. There is another, much rare condition characterized by redundant skinfolds and hair loss due to ectodermal dysplasia, dwarfism and SCID.

Antibody deficiency syndromes (Figure 2)

Following Bruton's first description of agammaglobulinemia in 1952, a large number of patients have been described with various patterns of antibody deficiency, ranging from an almost total absence of all isotypes to selective isotype and subclass deficiencies. Now that test immunization is becoming a routine diagnostic procedure, patients are being recognized with depressed antibody responses despite normal serum immunoglobulin levels. Some of the rare conditions are due to genetic defects on the X chromosome, while others are either single-gene or multigene autosomal defects.

The treatment is regular intramuscular, subcutaneous or intravenous immunoglobulin replacement therapy and antibiotics for infections.

X-linked agammaglobulinemia (XLA)

This disease is caused by mutations in a cytoplasmic tyrosine kinase (Bruton's tyrosine kinase – Btk) which is critical for the differentiation/proliferation of pre-B cells in the bone marrow. There are virtually no circulating surface positive IgM B lymphocytes and there is no antibody production, although cellular immunity remains intact. Autosomal recessive inheritance of mutations in the immunoglobulin μ -chain can cause a similar phenotype in females. The patients present with upper and lower respiratory tract infection, usually due to nontypable *Haemophilus influenzae*, in the first 2 years of life. Pneumococcal septicemia and meningitis may occur, and in the gut *Campylobacter* and *Giardia* infections are common; mycoplasma arthritis is an important but less common complication. There is usually an uneventful recovery from common viral infections, although enteroviruses, particularly echoviruses, may cause an ultimately fatal chronic meningitis. A few patients with X-linked agammaglobulinemia and growth hormone deficiency have been reported, but

Figure 2 Ontogeny of B lymphocytes. The blocks in differentiation/maturation in the antibody deficiency syndromes are as follows: A, X-linked agammaglobulinemia; B, common variable immunodeficiency μ -chain defects; C, selective IgA deficiency; D, X-linked immunodeficiency with hyper-IgM.

there is no molecular explanation for this and the growth hormone deficiency is probably secondary to hypothalamic/pituitary damage from viral infection.

X-linked immunodeficiency with hyper-IgM (X-HIM)

This is a very rare condition caused by mutations in the gene for CD40 ligand, a molecule which is expressed on the surface of activated $CD4^+$ T cells and which interacts with CD40 on B cells to enable switching from IgM to IgG/IgA production. Affected patients may also have neutropenia, and unlike XLA patients, are prone to opportunistic viral and fungal infection, sclerosing cholangitis and liver cancer.

'Common variable' immunodeficiency: CVID (synonym 'common variable' hypogammaglobulinemia: CVH or CVI)

This is usually a nonfamilial sporadic condition presenting at any age, particularly in the first few years of life and toward the end of the second decade. The criteria for diagnosis are not well defined, although in practice most patients have a serum IgG below 4 g l^{-1} , an IgA level below 0.1 g l^{-1} , and a serum IgM level below 0.2 g l^{-1} ; however some patients with less severe symptoms have IgM levels at the lower limit of the normal range and make significant amounts of specific IgM antibodies.

The circulating T lymphocytes in most patients fail to proliferate with antigens following immunization, and delayed hypersensitivity skin reactions cannot be induced *in vivo*. Many patients have a $CD4^+$ lymphopenia but opportunistic viral, fungal or protozoal infections are rare. There are genetic predisposing

factors in at least 20% of patients who have a first-degree relative with either CVID or IgA deficiency (IgAD), suggesting an autosomal dominant inheritance with incomplete penetrance. About 50% of patients share a common haplotype in the MHC complex on chromosome 6 (HLA-DR3⁺, C4A null, and a particular TNF polymorphism), but attempts to formally link genes to the MHC complex have so far failed. Variable blocks in B cell differentiation can be demonstrated *in vitro*, with most patients having normal numbers of circulating B cells expressing surface IgM, IgG and IgA. There is a defect in terminal differentiation of committed B cells into plasmablasts/plasma cells in the majority of patients *in vivo*, which can be partially overcome *in vitro* by adding recombinant IL-2, CD40 ligand and IL-10. It is unclear whether CVID is a group of separate disorders or a spectrum of a single disease, but the underlying defect seems to be in the $CD4^+$ (helper) T cell.

The pattern of infection is similar to that seen in XLA, but there are special features which include autoimmune disease, granulomatous splenomegaly and lymphadenopathy, lymphoid hyperplasia in the bowel, and a raised incidence of lymphoid and stomach malignancy.

X-linked lymphoproliferative syndrome (XLPS) (Duncan's disease)

The syndrome is due to an underlying inability to control Epstein-Barr virus replication, the gene being localized to Xq25 on the X chromosome. The clinical features vary, even within members of a single family, with some developing hypogammaglobulin-

emia, others Burkitt's-like B cell lymphomas, and some dying in childhood from fulminant infectious mononucleosis. No consistent cellular defect has been found to explain the disease. The obligate healthy heterozygotes usually have high levels of serum antibodies to EB viral capsid.

Thymoma and hypogammaglobulinemia

This nearly always affects patients over 40 years of age and is not familial. The severity of the hypogammaglobulinemia is variable, and is not reversed by removal of the tumor, which usually consists of spindle-shaped cells and is well encapsulated. Some patients lack circulating B lymphocytes and pre-B cells in the bone marrow, suggesting an effect on an early precursor, possibly due to an autoimmune reaction. Other associated autoimmune phenomena occur, such as myasthenia gravis, thrombocytopenia, neutropenia and red cell aplasia.

Selective immunoglobulin deficiencies

IgA deficiency (IgAD)

Defined as a serum IgA level of $<0.01 \text{ g l}^{-1}$. There are interesting geographical differences in prevalence, the deficiency occurring in 1 in 700 of Caucasians, but in only 1 in 18 000 Japanese. Most cases are sporadic, and in very rare cases deletions in the IgA heavy-chain gene cause the deficiency. In about 20% of IgAD cases, a first-degree relative has IgAD or CVID, suggesting a dominant inheritance and a mechanism similar to that of CVID. There is also an association, but no formal linkage, with the same haplotype in the MHC region which is associated with CVID. The circulating B cells in these cases express surface IgA but cannot differentiate into secreting IgA plasma cells.

Some patients suffer from recurrent respiratory infections, although usually they will also have poor IgG antibody responses following test immunization. The high incidence of serum antibodies to milk and other food proteins in affected adults seems to have no clinical significance, although there is evidence that low serum IgA levels in infants and young children predispose to symptomatic cows' milk allergy. There is an association between IgA deficiency and autoimmune/chronic inflammatory disorders, such as Still's and celiac disease.

IgG subclass deficiencies

IgG2 deficiency is the most common, and like IgA is normally late to develop in infants and young children. IgG2 deficiency is sometimes associated with IgAD, suggesting a similar mechanism. IgG1 tends to

compensate in the first few years of life, but this may fail temporarily and cause 'transient hypogammaglobulinemia of infancy' and recurrent infections. IgG2 deficiency may occur in about 1 in 1000 of the 'healthy' adult population, and can be associated with failure to respond to carbohydrate antigens, theoretically leading to a predisposition to infection with encapsulated organisms (e.g. pneumococci). IgG1, IgG3 and IgG4 deficiencies, either alone or in various combinations, have been described in association with recurrent infections. However, in general, there appears to be considerable cross-compensation within the subclasses; IgG4 probably has no clinical significance. Mutations in the relevant heavy-chain genes have been described in a few families, but usually the defect is due to a failure of terminal B cell differentiation for the particular subclass.

Selective IgM deficiency

This is very rare as a primary disorder, and most cases have been found by chance when screening hospitalized patients with a variety of conditions. Excess suppression of IgM synthesis *in vitro* by T lymphocytes has been shown in some patients, possibly triggered by infection or drugs. Recurrent infections are unusual since IgG and IgA compensates.

κ chain deficiency

A rare defect due to mutations in the κ chain genes which has no clinical significance.

Disorders associated with partial immunodeficiency

Wiskott-Aldrich syndrome (WAS)

This X-linked disorder is characterized by thrombocytopenia, eczema, recurrent infections, and a high incidence of B cell lymphomas at an early age. The WAS gene has been cloned and its product (WASP) probably has a role in cytoskeletal organization and glycosylation of a number of surface proteins; absence of lymphocyte sialophorin (CD43) is a useful screening test. Patients have a very poor antibody response to polysaccharides, frequently have depressed IgM but high serum IgE levels, and a progressive functional defect in T cells.

Chediak-Higashi syndrome

This is an autosomal recessive condition characterized by albinism and large cytoplasmic lysosomal granules in the white cell series which compromise neutrophil movement and phagocytosis. T and B lymphocyte function is not significantly impaired, but severely depressed NK activity may account for

the pancytopenic crises which are thought to be caused by viral infection.

Mucocutaneous candidiasis

Although this can occur in SCID, there is a rare distinct disorder, which is sometimes familial, where there is a selective failure to control *Candida* infection. Patients have variable abnormal immune responses to *Candida* antigens, but the basic mechanism is not understood.

DNA repair defects

There are a variety of autosomal recessive genetic diseases caused by defects in the excision/repair of DNA which has been damaged by chemicals, ionizing and UV irradiation. Cell lines from such patients show chromatid damage when exposed to these agents *in vitro*. The common theme is a high incidence of malignancy at a young age, particularly lymphomas.

Ataxia telangiectasia (AT)

Patients suffer from infection, premature aging of the skin (pigmentation, telangiectasia), and severe ataxia due to cerebellar degeneration. The AT gene has been cloned on chromosome 11 and is a kinase (with homology to phosphatidylinositol 3-kinases) which is involved in DNA repair and cell cycle regulation. Lymphoma and other solid tumors are common; heterozygotes, which account for about 2% of the population, are also predisposed to malignancy. There are variable immunoglobulin deficiencies, selective IgA deficiency being common. There are functional T lymphocyte defects, the most consistent being a failure to generate cytotoxic T cells to viral-infected autologous cells.

Nijmegen-Breakage syndrome

A similar but distinct disease to AT, but without ataxia and associated with microcephaly, 'bird-like' facial features, mental and growth retardation. The immunological defects are similar to those of AT.

Ligase I defect

Only one patient has so far been reported with inherited mutations in the ligase I gene. She had severe growth retardation, recurrent infections due to partial cellular and humoral immunodeficiency and skin sensitivity to sunlight; she died from lymphoma at 19 years.

Bloom's syndrome

This is characterized by growth retardation, skin sensitivity to UV light and cancers in childhood or adolescence. The relevant gene has homology with RecQ helicases. There are variable defects in immunity, but frequently poor or absent *in vitro* lymphocyte proliferation with a variety of stimuli, and low levels of IgM.

Xeroderma pigmentosum (XP)

There is a defect in excision repair of UV-damaged DNA, associated with skin pigmentation and a high incidence of cutaneous malignancies. Affected patients have subtle immune defects with depressed NK lymphocyte activity, possibly due to depressed interferon γ production; they are not particularly prone to infection.

IMMUNODEFICIENCY, SECONDARY

A David B Webster, Department of Clinical Immunology, Royal Free Hospital School of Medicine, University of London, London, UK

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Although the term 'secondary' is unsatisfactory and in the future is likely to be replaced by a more descriptive classification, secondary immunodeficiency is used to describe most of the immunodeficiency disorders that are not due to inherited single gene defects of lymphocyte function, with the important exception of 'common variable' immunodeficiency (CVID) and selective immunoglobulin A (IgA) deficiency, where the mechanism remains obscure. Secondary immunodeficiency embraces a wide range of lymphocyte disorders, from those associated with lymphoid malignancy, to those induced by viruses and the immunodeficiency related to prematurity and old age (Table 1). There are a large number of drugs which can cause partial immunodeficiency; this has been difficult to study because the drugs are often given against a background of existing immunodeficiency associated with malignant or autoimmune diseases.

In contrast to the 'primary' immunodeficiencies, secondary immunodeficiency cannot be conveniently subclassified into those affecting either antibody production or cellular immunity, since there is usually a mixed picture. It is more useful to subclassify the disorders according to the type of disease with which they are associated (e.g. viral infections, malignancy). Most of the disorders described here are associated with *in vitro* functional abnormalities of T lymphocytes, usually depressed T cell proliferation with mitogens; depressed delayed hypersensitivity skin reactions to recall antigens (tuberculin, candida) is also common. Throughout this article, the term 'functional T cell defects' will be used to describe these phenomena.

Secondary immunodeficiency and malignancy

Chronic lymphatic leukemia (CLL)

This is one of the most important causes of immunodeficiency because survival is usually prolonged and correction of the immunodeficiency improves the overall prognosis. More than half of affected patients develop severe antibody deficiency and hypogammaglobulinaemia, which tends to become more severe as the disease progresses. The mechanism is unclear, with some workers suggesting that the expansion of the malignant lymphocyte clone, which is usually a

Moderate (+) or severe (++) deficiency.

B cell, disorganizes the architecture of lymph nodes, spleen and bone marrow, thus preventing cellular interactions needed for the induction of antibody responses. Others have shown that either the B cell clone and/or natural killer (NK) cells from affected patients will suppress *in vitro* immunoglobulin production by normal B cells, although this may not be

a direct effect. The antibody deficiency is of clinical importance, since early treatment with immunoglobulin replacement therapy will improve the quality of life by preventing chronic bronchitis and bronchiectasis.

Multiple myeloma

Most patients have a clinically significant depression of polyclonal antibody production which predisposes to pneumonia and septicemia with capsulated organisms (e.g. pneumococci). Although patients with myeloma can survive some years with modern chemotherapy, recent trials suggest that immunoglobulin replacement therapy neither influences morbidity nor survival, possibly because antibody production tends to normalize during remission. The mechanism of the antibody deficiency is unclear, but there is evidence that the malignant plasma cells, as well as monocytes from myeloma patients, will suppress normal B cell proliferation *in vitro*, possibly through depression of interleukin 1 (IL-1) and IL-2 synthesis. Light chain isotype suppression, whereby polyclonal B cells carrying the same light chain as the malignant clone are suppressed, is also not understood but is thought to reflect a partially successful control mechanism for the malignant clone itself.

Lymphomas

Mild to moderate defects in both cellular and humoral immunity are associated with a variety of lymphoreticular malignancy and lymphocytic leukemias, functional T cell defects being particularly well described in Hodgkin's disease where survival may be prolonged. However, no clear patterns of immunodeficiency in the various lymphomas have been documented, and the picture is usually confused by concomitant chemotherapy.

Nonlymphoid tumors

There is much interest in defects in 'immune surveillance' which may precede or are secondary to a variety of malignant tumors. Suppression of IL-2 synthesis may be important, and a number of therapeutic trials with recombinant IL-2 are in progress. There is still no clear evidence that immunodeficiency contributes either to the development of cancer or a poor prognosis.

Nutritional deficiencies

Protein calorie malnutrition

Malnutrition in the Third World is an important predisposing factor for infectious disease, which is the

major cause of death, particularly in young children. Susceptibility to tuberculosis and recovery from measles infection are particularly influenced by nutritional status, probably through an effect on cellular immunity. Vitamin deficiencies are an important cofactor. There is evidence that vitamin B₁₂ deficiency may be a predisposing factor for tuberculosis in Asian communities in the West, and studies in the Third World suggest that vitamin A supplementation reduces the infection rate in children.

Severe deficiency of vitamin B₁₂, due to an autosomal recessive genetic deficiency of transcobalamin II, a transport protein, affects a variety of bone marrow-derived cells, causing neutropenia, B cell abnormalities with hypogammaglobulinemia, and megaloblastic anemia. Vitamin B₁₂ injections will correct the deficiency.

Metals and trace elements

Iron deficiency is common and not usually associated with a predisposition to infection. However, there is a link with chronic mucocutaneous candidiasis where it appears to be a cofactor for infection, sometimes with endocrine abnormalities. A deficiency of zinc, critical for many enzyme functions, will compromise T cell function and predispose to opportunistic infections. Acrodermatitis enteropathica is a rare autosomal recessive genetic disorder causing a partial defect in zinc absorption from the gut; affected patients suffer from dermatitis, malabsorption and infections, which can be corrected by zinc supplements. Selenium may be an important trace element for T cell function, and it is claimed that a partial deficiency in children may predispose to infections.

Bone marrow transplantation

B lymphocyte function in allogeneic bone marrow transplantation is slow to recover, and patients may need immunoglobulin therapy for many months. Autologous T lymphocyte-depleted transplantation (e.g., for leukemia, scleroderma) is followed by a profound lymphopenia which recovers after a few months. Because the thymus is relatively inactive in transplanted adults, it is possible that the T cell repertoire is reconstituted by CD4 and CD8 T cells from the gut-associated lymphoid tissue.

Prematurity and aging

There are two similarities in the immunodeficiency associated with the two extremes of life. Premature low birthweight infants are prone to fatal infections

with a variety of bacteria, particularly gram-negative gut commensals with their endotoxins. Although the defects may involve a variety of cell types, including neutrophils, antibody deficiency is important, particularly the inability to produce antibodies against bacterial capsular polysaccharides and endotoxins. Even full-term normal weight infants usually fail to make antibodies of the IgG2 subclass against polysaccharides, and many will also fail to compensate with an IgG1 response. This explains the failure of polysaccharide vaccines to meningococci and *Haemophilus influenzae* type B to stimulate protective antibodies in the first 2 years of life. Antibody production to polysaccharides is also depressed in old age, probably explaining the increased susceptibility to pneumococcal septicemia in those over 80 years.

Many studies have demonstrated minor changes in T cell subsets and function in aged subjects. It is unclear whether these changes have any relevance to the predisposition to malignancy in this age group. However, subclinical immune dysregulation is common, as shown by the frequency of serum autoantibodies and paraproteins.

Drug-induced immunodeficiency

Most cytotoxic drugs used in the treatment of malignancy depress cellular and humoral immunity but this tends to be overridden by the neutropenia which often occurs with prolonged therapy, and which predisposes to gram-negative bacterial septicemia and fungal infections. Immune defects due to these drugs may become of greater clinical significance now that hematopoietic growth factors can be used to prevent the neutropenia. Steroids, cyclophosphamide and azathioprine commonly depress cellular immunity, and can depress immunoglobulin levels after prolonged usage. The clinical significance of these defects is difficult to determine, since the drugs are usually given for conditions (vasculitis, autoimmune diseases) where there may be an underlying defect in immune regulation. However, long-term treatment, particularly with azathioprine, may predispose to fatal opportunistic infections. Cyclosporine, now being used in autoimmune diseases as well as to prevent graft rejection, suppresses antigen receptor triggering of T lymphocytes. This, and other drugs used to prevent transplant rejection can also depress immunoglobulin levels, and some clinics are routinely using immunoglobulin replacement therapy following organ or bone marrow transplantation.

There is evidence of permanent CD4 T cell depletion in adolescents and adults given chemotherapy for leukemia, although CD8 T cells recover.

The later the chemotherapy is given in life, the more profound the CD4 T cell lymphopenia, which is explained by the relative failure of thymic activity with increasing age.

Gold, sulfasalazine, penicillamine, and phenytoin have each been implicated in the development of selective IgA deficiency, and in some cases panhypogammaglobulinemia. Discontinuing the drug usually leads to recovery of immunoglobulin levels, although this may take some years. Spontaneous recovery from CVID, which is the differential diagnosis, is extremely rare, a fact which strongly supports the view that these drugs can cause hypogammaglobulinemia. The mechanism is obscure, and no direct effect on B lymphocyte proliferation or differentiation *in vitro* can be demonstrated with doses of the drug likely to be achieved *in vivo*. The effect is idiosyncratic, since less than 1% of patients receiving these drugs develop any sign of immunodeficiency.

Drug-associated immunodeficiency is partly responsible for the raised incidence of selective IgA deficiency in juvenile rheumatoid arthritis and systemic lupus erythematosus, but there may be other factors which link immunoglobulin deficiencies with autoimmune disease in general. This link may lie in the major histocompatibility complex (MHC) region on chromosome 6, since patients with these diseases, and with CVID, frequently share a common haplotype.

Viral-induced immunodeficiency

Human immunodeficiency virus

HIV-1 and HIV-2 are human retroviruses which replicate in T cells and macrophages, causing gradual attrition of cellular immunity, and depression of antibody production in the terminal stages of the disease. The opportunistic bacterial, fungal, and viral infections associated with the acquired immune deficiency syndrome (AIDS) are probably due to functional defects in macrophages, although the mechanism is still unclear.

Rubella virus

Some infants with the congenital rubella syndrome do have persistently low serum IgG and IgA levels, associated with chronic excretion of rubella virus after birth and the presence of specific IgM anti-rubella antibody. The hypogammaglobulinemia may persist after the virus is eliminated. The mechanism is unclear.

Herpes viruses: cytomegalovirus (CMV)

There is no evidence that the Epstein-Barr virus (herpesvirus 4) causes immunodeficiency, apart from the hypogammaglobulinemia which occurs in the X-linked lymphoproliferative syndrome. However, cytomegalovirus (herpesvirus 5) does itself cause significant immunodeficiency when it becomes reactivated in immunocompromised patients, particularly following bone marrow or organ transplantation. CMV replicates in macrophages and stimulates the proliferation of CD8⁺ T cells which may suppress both cellular and humoral immunity. There is evidence suggesting that IL-1 and IL-2 secretion is depressed in monocytes and lymphocytes respectively, although the mechanism is unknown. Furthermore, CMV itself may bind to β_2 -microglobulin and could dysregulate the immune response through an effect on class I molecules.

Trauma/surgery/thermal injury

Severe trauma is usually associated with significant immunosuppression which may determine prognosis. Prophylactic antibiotics usually prevent bacterial sepsis, but CMV reactivation and fungal pneumonia may occur due to depression of cellular immunity. A variety of mechanisms are involved, with prostaglandin release from monocytes downregulating T cell function, together with other factors causing suppression of IL-1 and IL-2 synthesis. Antibody production may also be depressed but this is rarely clinically important.

Relatively minor (<10% surface area) thermal injury in young children selectively depresses IgG2 and IgG3 serum immunoglobulin levels, although more severe burns in both children and adults suppress all antibody responses. It is not clear whether this is due to decreased synthesis or increased catabolism. The clinical significance is uncertain and cannot be tested in the West because of the effective use of prophylactic antibiotics. However, fatal endotoxemia following burns in the Third World is common, and can be prevented with passively administered antibodies.

Splenectomy/thymectomy

Splenectomy predisposes to septicemia/meningitis with pneumococci, meningococci, or *Haemophilus influenzae* bacteria. Following post-traumatic splenectomy, <5% of patients will develop septicemia, but this rises to 25% when splenectomy is carried out for other reasons (e.g. Hodgkin's disease, autoimmune hemolytic anemia). Congenital asplenia and multiple splenic infarction in sickle cell anemia car-

ries a similar risk, and all patients are advised to take prophylactic penicillin. The mechanism is not clear but is probably due to a combination of a failure to trap bacteria within the splenic reticuloendothelial system and the consequent failure to generate specific antibodies fast enough to limit the infection. Vaccination of affected patients with polysaccharides from the relevant organisms is theoretically justified, preferably before splenectomy.

There are no good data on the effect of thymectomy in infancy, but this is unlikely to be clinically significant. Most of the studies have been done on adults thymectomized for myasthenia gravis when there is a small fall in the numbers of circulating T cells, with no effect on the level of antibodies to common organisms.

Metabolic disorders

It is not surprising that severe metabolic disorders such as renal and liver failure are associated with depressed immunity, with pneumonia being a common terminal event. Death from infection in infancy is also common in many of the severe inherited metabolic defects, although it is usually inappropriate to investigate this in any detail. In some cases, a metabolic defect may retard the normal development of immunity in infants, such as the reported hypogammaglobulinemia in a few infants with uridine monophosphate synthase deficiency (orotic aciduria). On the other hand, genetic defects in enzymes involved in the synthesis of biotin, an important cofactor for a variety of carboxylases, leads to a moderately severe combined immunodeficiency affecting both cellular and humoral immunity, with mucocutaneous candidiasis being a characteristic clinical problem.

Increased loss/catabolism of immunoglobulins

Nephrotic syndrome/protein-losing enteropathy

Loss of proteins through the kidneys in the nephrotic syndrome often causes moderate hypogammaglobulinemia, usually with a low serum IgG and IgA; the IgM level remaining normal presumably due to its higher molecular weight. However, not all the IgG subclasses are equally affected, with IgG3 and IgG4 remaining at normal levels. This cannot be explained by differences in the molecular weights of the IgG subclasses and suggests that factors other than glomerular leakage play a part. The antibody deficiency is not usually severe, but is probably responsible for the predisposition to pneumococcal septicemia described in early textbooks.

Protein-losing enteropathy is a rare complication of chronic inflammatory bowel disease (e.g. Crohn's) or chronic bacterial infection (e.g. Whipple's disease). Another cause is intestinal lymphangiectasia where there is a dilatation of the mucosal lymphatics with loss of protein and lymphocytes. This is caused by lymphatic obstruction due to infection (e.g. tuberculosis), malignancy (e.g. lymphoma), or increased hydrostatic pressure in severe congestive heart failure. There is also a primary genetic disorder of lymphatic vessels which can affect the gut. IgG and IgA are usually moderately depressed and infections are unusual; the T cell lymphopenia and the associated functional defects in cellular immunity are clinically unimportant. A diet high in medium-chain triglyceride can reduce lymphatic flow and alleviate symptoms, but otherwise surgery may be necessary to remove the affected area of bowel.

Dystrophia myotonica is the only well-characterized condition where there is a selective increase in the catabolism of serum IgG, although the IgG level is only moderately depressed. Although this autosomal dominant condition primarily affects muscles, it must also affect the uptake and/or degradation of IgG by macrophages, although this has not been formally demonstrated.

IMMUNODIFFUSION, SINGLE RADIAL

George Feinberg, formerly of The Rayne Institute, The United Medical Dental School, London

As the term implies, immunodiffusion refers to an *immunological reaction* in which the reactants *diffuse* into a supporting medium, i.e. a gel. The reaction involved is that of precipitation, the objective being to visualize and immobilize an *in vitro* reaction between a precipitating antibody and a soluble antigen. Thus, immunodiffusion is a modification of the precipitin reaction first observed in fluid media by Kraus in 1897. As one of the reactants is placed in wells cut in the gel, the diffusion is radial.

As commonly practised, immunodiffusion is carried out in either of two forms: double diffusion and 'single radial immunodiffusion' (SRI; also RID, i.e. radial immunodiffusion). In double diffusion, both antigen and antiserum diffuse from wells in the gel, whereas in SRI one reactant – usually the antibody – is included in the gel and only the other diffuses in.

Thus, in double diffusion precipitation lines are formed in the gel where antigen and antibody from juxtaposed wells overlap; while in SRI the precipitate takes the form of a ring round the well.

SRI may be traced back to the observation of Petrie in 1932 that a ring of precipitate formed round a colony of an exotoxin-producing bacterium growing on agar which contained the specific antitoxin. In 1949, Ouchterlony and Elek independently adapted this observation to produce a double immunodiffusion technique. Wells were produced in an agar plate, using a template or cutter. Individual wells received either antigen or antiserum. As the two reactants diffused into the gel, a line of precipitate formed within the zone of overlap. This has become a most useful qualitative technique for demonstrating and comparing antigens and

Figure 1 Assay of an antigen from the straight line plot of D^2 versus concentration on arithmetic graph paper.

antibodies, but proved inadequate for quantitative determinations.

Simultaneously, Oudin was transferring Petrie's observations to a tube, showing that rings of precipitate would form in a gel containing antiserum when it was overlaid with a solution of the corresponding antigen. This was *single* linear diffusion, as for the purpose of the method only the antigen diffusion was of consequence. It was a dynamic system, the precipitate rings migrating linearly down the gel with time; thus, single linear immunodiffusion. As the rate of the ring migration was determined by antigen concentration, it could be used (albeit not very conveniently) for quantification of antigens against known standards.

In 1957, to achieve a more convenient immunodiffusion assay system, Feinberg combined Oudin's tube single diffusion with the Ouchterlony-Elek plate to produce a *single radial immunodiffusion* system.

As in Oudin's technique, serum was incorporated in a molten gel, but as with Ouchterlony-Elek the gel was poured into a plate and allowed to set. With a specially designed gel cutter, uniform wells were cut in the antiserum-gel and filled with antigen solution, using standard concentrations of the antigen for comparison with test antigens. Diffusion of antigen and formation of the precipitate rings were allowed to go to completion, assay being based on a limiting dilution end-point, i.e. the lowest concentration of antigen showing a ring of precipitate.

In 1963, Tomasi and Zigelbaum modified the Feinberg technique, eliminating the need to achieve an end-point. More conveniently, they measured the diameters of the precipitate rings by placing a transparent ruler beneath the plate and plotting the diameters against antigen concentrations. With suitable standards they were able to assay secretory immunoglobulin A (IgA) in saliva, colostrum and

urine. In 1965, Fahey and McKelvey confirmed the validity of the system and used it to measure levels of immunoglobulins in serum.

In 1965, Mancini and coworkers extended observations to include a diversity of antigens, simultaneously observing the reliability of SRI assay and noting that it was not influenced by variations in temperature. However, in their estimation, merely recording ring diameters could give erroneous results. They advocated projection of the rings on to strong paper, outlining the projected rings with pencil, cutting the paper discs outlined and weighing them. This so-called 'Mancini technique' proved to be cumbersome, as subsequently acknowledged by Heremans. Because of this, in practice it has largely been abandoned, whereas the Tomasi and Zigelbaum modification of the Feinberg technique has generally been adopted as the method of choice and now forms the basis of commercially supplied immunodiffusion plates for the immunoassay of proteins in plasma and body fluids.

Though SRI is most widely used for the assay of antigens, Feinberg observed it could also be used for the assay of antibodies, for which purpose the placing of the reactants is reversed: the antigen is incorporated in the gel, while dilutions of antibody are placed in the wells, i.e. reversed single radial immunodiffusion (RSRI). This was confirmed by Vaerman and colleagues in 1969.

Mechanisms

When antigen diffuses radially into a gel containing antiserum, immune complexes are formed and a precipitate begins to deposit as a ring at the interface between the two reactants. The higher the concentration of antigen in the well, the more rapidly precipitation takes place, i.e. rings appear sequentially in direct relationship to antigen concentration. Ongoing diffusion of antigen from the well builds up the precipitate at the outer edge of the ring, where the antigen encounters additional antibody. Therefore, the system is initially in a dynamic state in which the rings increase in size with time. A static stage is reached when all the antigen has diffused into the gel and precipitation is complete. At this stage, the rings are most distinct and remain constant in size, so readings can conveniently be taken at any time thereafter.

The time to reach the static state and the ultimate size of the rings are dependent on the molecular size of the antigen, as well as the antigen concentration. The larger the molecule, the longer the time and the smaller the ring. As these are constants for any one antigen and apply equally to standard and test anti-

Figure 2 Measuring ring diameter with the convenient wedge-shaped rule.

gen, they do not ordinarily interfere with the validity and accuracy of SRI. However, they do become significant factors when assaying antigens which exist in different polymeric forms, or which tend to complex with other proteins, so one must remain aware of such possibilities.

At the static stage, the area circumscribed by the ring is proportional to the concentration of the antigen in the well. Since area is proportional to the square of the radius (and, hence, to the square of the diameter, D), then the square of the diameter (D^2) of the ring is proportional to the concentration of antigen. Such being the case, plotting D^2 against concentration on arithmetic graph paper will produce a straight line (Figure 1). Alternatively, to avoid the requirement of calculating D^2 , semilog graph paper may be used, plotting D itself on the linear scale against antigen concentration on the log scale.

Methodology

SRI is generally carried out in an agarose gel. The molten gel is cooled to $\sim 50^\circ\text{C}$ to avoid heat denaturation of the antiserum, which is warmed to a similar temperature and added to the molten gel in desired concentration. The two are mixed gently, but thoroughly, and poured into a dish, or on to a glass plate (e.g. a microscope slide), supported on a perfectly horizontal surface to ensure uniform gel thickness. When the gel has set, wells are cut using a sharp cutting instrument designed for the purpose. Alternatively, a plastic mask with a pattern of holes can be floated on the molten gel, which is then allowed to set to form a firm seal between mask and gel. In this case, wells need not be cut, the antigen solution being applied to the exposed areas of gel.

Three known standards, spanning the anticipated range of concentrations of the test samples, are used along with the test samples. Uniform measured volumes must be used throughout. Alternatively, when wells are used, comparable volumes can be achieved by filling each well until the meniscus just disappears;

this is preferable if the gel may not be of uniform thickness.

The plates are incubated in a humid atmosphere, preferably until ring formation is complete. Measurement of the ring diameters may be done with a transparent ruler or, more conveniently, with the wedge-shaped scale introduced by McSwiney (Figure 2). Mechanical aids for reading ring diameters are also available commercially. These include a modified jeweller's eye-piece with an in-built graduated scale. Most sophisticated and best suited for making large numbers of readings routinely is an electronic plate-reader.

For the purpose of assay, graphs are constructed, as described above, from three standard dilutions. The ring measurement of each test sample is then positioned on the graph and the corresponding concentration read off.

Investigating the sensitivity and accuracy of SRI in 1965, Mancini and colleagues reported that as little as $1.25\ \mu\text{g}$ of antigen could be measured when using $2\ \mu\text{l}$ samples of antigen solution. They found the standard deviation of SRI antigen assays to be less than 2% of the mean.

IMMUNODOMINANCE

Luciano Adorini, Roche Milano Ricerche, Milan, Italy

Antigens are molecules recognized by specific T and B cells. In defining antigens two properties should be distinguished: immunogenicity, the capacity of a given antigen to induce an immune response, and antigenicity, the capacity of the antigen to be recognized by the antigen-specific receptors expressed by T and B cells. Therefore, every immunogen is also an antigen but not all antigens are immunogens. Antigens are constituted by antigenic determinants or epitopes. In proteins, which represent the vast majority of antigens, two types of antigenic determinants can be distinguished: continuous or segmental determinants, entirely contained in a continuous primary sequence of amino acid residues, and discontinuous or assembled determinants, formed by residues distant in the primary sequence but topographically assembled in the tertiary structure of proteins. These definitions have substituted the obsolete distinction between sequential and conformational determinants, since sequential determinants also interact with their specific receptor in a preferential conformation. The combining site of antigen-specific T and B cell receptors consists of a three-dimensional arrangement of amino acid residues, and therefore, among the many conformations of a polypeptide antigen, e.g. a synthetic peptide, some will be bound with higher affinity. Thus, the three-dimensional architecture of the combining site defines the conformation of the most complementary antigen and in this sense all antigenic determinants are conformational. Some antigenic determinants, either because of characteristics intrinsic to the antigen and/or to the immunized individual, become immunodominant, representing epitopes preferentially recognized by T and B cells of a given individual after immunization with the entire protein.

Antigen recognition by T and B cells

T and B cells recognize antigen in a fundamentally different way. Whereas antibodies (hence also antigen-specific B cell receptors) recognize soluble proteins in their native three-dimensional conformation, antigen-specific T cell receptors recognize a binary complex formed by an antigenic determinant bound to molecules encoded by the major histocompatibility complex (MHC). Antigen recognition by T cells is therefore not direct, as for antibodies, but takes place after protein internalization and partial proteolytic degradation in cells capable of antigen

processing and presentation (e.g. macrophages, dendritic cells and B cells), which then express on the cell surface complexes formed by T cell determinants bound to MHC molecules. These different recognition mechanisms explain why antibodies, interacting with native proteins, preferentially recognize assembled determinants, whereas T cells predominantly recognize sequential determinants of about 8–15 residues, derived from the limited degradation of protein antigens.

Immunodominant T cell determinants

T cells recognize antigens as peptides associated with self molecules encoded by the MHC, and therefore the binding of immunogenic peptides to MHC molecules is a prerequisite for T cell activation. Each MHC glycoprotein has a single binding site for peptides and, because the number of antigenic peptides to be presented to T cells is very large, each MHC molecule must have the ability to bind many peptides of unrelated sequences – for example, several of those generated by the processing of a single protein antigen. It would thus be expected that T cells respond to several different epitopes on a single foreign protein; however, T cell responses are generally specific for a few, and often only one, of the peptides derived by processing of a protein antigen. These T cell epitopes are referred to as immunodominant. Immunodominance of selected T cell epitopes has been demonstrated for several proteins, including cytochrome *c*, lysozyme, myoglobin, ovalbumin, influenza virus hemagglutinin, staphylococcal nuclease, ragweed allergen, bacteriophage λ repressor and acetylcholine receptor. Epitope immunodominance has been studied mostly in class II MHC-restricted T cell responses, but it is also present in class I-restricted cytotoxic T cell responses.

Thus, although many potential T cell determinants may exist within a given protein antigen, the T cell response of a given individual is focused on a few selected ones. Determinants eliciting the most vigorous immune responses following priming with protein antigen are defined as dominant, while those stimulating weaker responses are termed subdominant. In addition, a third class of T cell determinants exists, the cryptic epitopes. These determinants correspond to peptides which are themselves strongly immunogenic yet do not recall a significant response after immunization with the native protein, implying

inefficient generation of naturally processed epitopes corresponding to these determinants.

The molecular events involved in antigen processing are still poorly understood, but the emerging view indicates that, in general, protein antigens undergo a limited degree of proteolysis in an acidic intracytoplasmic compartment, the resulting peptides associate with MHC molecules and are transported to the cell surface complexed with these molecules. In antigen presentation by MHC class II molecules, the first event in antigen processing probably consists in unfolding of the native protein antigen. Unfolded polypeptide antigens bind to class II molecules. Polypeptide regions external to the MHC binding site are then trimmed by proteolysis, while the bound determinant remains protected. This view stresses the importance of intramolecular competition between determinants on the same polypeptide for binding to an MHC molecule and of competition between different MHC class II molecules, e.g. I-A and I-E, for binding to the unfolding protein antigen. Accordingly, several mechanisms can be anticipated to influence the immunodominance of T cell determinants: 1) availability of a given epitope after unfolding of protein antigen; 2) its ability to bind to MHC molecules; 3) competition between different epitopes from the same protein antigen (or other proteins) for binding to MHC molecules; and 4) presence in the repertoire of T cells able to recognize the peptide-MHC complex. All these mechanisms can operate during the T cell response to a given protein antigen, as exemplified by the emergence of T cell determinants in the response to hen egg-white lysozyme (HEL).

In this case, the immunodominance of T cell determinants was studied by analyzing the correlation between binding of a series of synthetic peptides encompassing the entire HEL sequence to class II molecules of the H-2^k haplotype, and T cell responsiveness to these peptides. After HEL priming, three immunodominant T cell epitopes were found: two were recognized in association with I-A^k molecules and one with I-E^k molecules. Accordingly, these peptides bound to the appropriate class II molecule. Several other HEL peptides, although capable of binding to class II molecules, were not immunodominant, and this could be accounted for by: 1) failure to generate the peptide during antigen processing; 2) competition by an immunodominant peptide for presentation *in vivo*; and 3) an inherently poor capacity of the T cell repertoire to respond to a particular peptide-MHC complex.

Therefore the immunodominance of T cell determinants results from: 1) intrinsic characteristics of the epitope, e.g. the presence of structural motifs

allowing binding to MHC molecules; 2) characteristics of the immunized individual, e.g. the presence of appropriate MHC molecules and T cell receptors; and 3) events related to antigen processing and presentation, e.g. competition between different epitopes of a given protein antigen for the available MHC binding sites. Immunodominance is not due to the pre-emption of the response by a single dominant T cell clone, and actually immunodominant epitopes are usually the focus of a polyclonal T cell response. The combination of all these levels of influence determines the final pattern of immunodominant T cell determinants, and a given protein injected in different individuals will give rise to distinct immunodominant epitopes. Understanding the mechanisms influencing immunodominance in protein antigens of pathogenic microorganisms is obviously critical in the development of effective vaccines.

Immunodominant T cell epitopes can be defined not only in the response to foreign proteins, but also in the anti-self response. During the response to foreign proteins immunodominant epitopes tend to remain constant, whereas they may change during the response to self antigens. A dynamic model of immunodominance in autoimmunity, based on the recognition by autoreactive T cells of novel immunodominant epitopes during the course of disease, has been proposed. This phenomenon has been referred to as determinant spreading. The emergence of novel immunodominant epitopes may be due to alteration in self antigen presentation that leads to the display of previously cryptic self determinants.

Immunodominant B cell determinants

Unlike T cells, B cells recognize many determinants as immunodominant on the surface of a protein antigen. Most determinants depend upon the conformational integrity of the native protein, and those to which an individual responds are dictated by the structural differences between the antigen and the host's self proteins and by the cellular regulatory mechanisms of the host, as well as by inherent properties of the protein molecule.

Thus, a nearly limitless spectrum of antibodies can potentially be induced, but in a given individual only some of the many specifically reactive B cell clones are activated. In the case of cytochrome *c*, a slowly evolving protein, the limited sequence differences between each cytochrome *c* molecule and that of the responding host restricts the number of determinants favoring the expression of immunodominant epitopes. However, the fact that most substitutions are immunologically detectable in some hosts indicates that all the surface protein is immunogenic in the

species. This is similar to the situation observed with T cell determinants. In any given individual few, and often only one, determinant becomes immunodominant for T cells, but at the species level (for example, considering all the available mouse strains with different MHC haplotypes) any protein determinant can be usually shown to be immunodominant in some hosts. However, as discussed before, immunodominance is defined by the immune response of an individual immunized with a given protein. Therefore, in this sense, immunodominant determinants can also be defined for B cells.

The interest in identifying immunodominant B cell determinants derives from their possible use in synthetic vaccines, which should be ideally composed of both T and B cell determinants, since in most cases these would not overlap. Besides many immunoregulatory mechanisms, largely T cell dependent, intrinsic characteristics of the antigenic determinant, such as accessibility, hydrophilicity and mobility, also influence the immunodominance of B cell epitopes. Although most B cell protein epitopes are discontinuous, the emphasis on continuous epitopes is due to the potential usefulness of predicting which linear peptide fragments are likely to possess cross-reactive antigenicity with the intact protein. Since for most proteins the only available structural information is their amino acid sequence, identification of short linear sequences, mimicked by synthetic peptides, representing immunodominant epitopes of the native antigen is currently the only practical approach.

IMMUNOELECTROPHORESIS

Anna-Brita Laurell, Department of Medical Microbiology, Section of Clinical Immunology, University of Lund, Lund, Sweden

The term immunoelectrophoresis, or electroimmunoprecipitation, which is sometimes used synonymously, refers to any of a series of methods where immunoprecipitation is obtained after electrophoretic separation of proteins in an electric field. Based

on differences in antigenic composition and charge, these methods make possible identification and quantification of proteins with a molecular weight of 5–10³ kDa or more.

Immunoelectrophoresis was first coined by Grabar

and Williams in 1953. After electrophoretic separation of serum proteins in an agar gel, the serum proteins were allowed to diffuse against antibodies, leading to a pattern of precipitation arcs in the agar representing the major constituents among the serum proteins. Thus the globulin fractions known at that time, the α -, the β - and the γ -globulins, were found to contain several distinct proteins, the main components of which have since been distinguished as α_1 -antitrypsin, α_2 -macroglobulin, transferrin, C3, immunoglobulin G (IgG), IgA and IgM. Immunoelectrophoresis created a breakthrough in protein identification and in immunology.

Crossed immunoelectrophoresis

The disadvantage of the original immunoelectrophoresis was the long second diffusion step, whereby the primary separation of the various proteins was partially masked, leading to overlapping between molecular species with antigenic similarity and similar electric charge. This was overcome by development of crossed immunoelectrophoresis, where the primary electrophoretic step was followed by forcing the separated proteins by an electric field into a second gel containing antibodies against the various proteins. When protein antigens react with their corresponding antibodies in specific ratios, distinct and narrow precipitation arcs are formed. Crossed immunoelectrophoresis is a sensitive technique, making visible differences in charge and/or antigenic composition between proteins otherwise difficult to identify or separate. The method is valuable for the analysis of heterogeneous protein populations, for studies of genetic polymorphism, for identifying structural changes upon degradation of proteins and the identification of the fragments formed, and for analysis of protein-protein complexes and enzyme-inhibitor interactions. Thus, for instance, α_1 -antitrypsin variants are recognized, the presence of cleavage products of C3 – C3b, C3c and C3d – can be shown, and enzyme-inhibitor complexes such as those containing antithrombin III or α_1 -antitrypsin or C1 inhibitor (C1 inactivator) can be analyzed.

The composition of the C1 complex of the complement system can be demonstrated by crossed immunoelectrophoresis with monospecific antibodies against the subcomponents C1q, C1r and C1s, respectively. When fresh normal serum was run with Ca^{2+} present in both electrophoretic steps, the native C1qrs complex remains at the application site and no visible precipitate appeared with anti-C1q, anti-C1r or anti-C1s in the second gel. When the second electrophoretic step was done with EDTA present, two separate precipitation arcs appeared at the appli-

cation site, representing C1r and C1s which have dissociated from C1q. The dissociated C1q subcomponent migrated towards the cathode and gave rise to a cathodic precipitate when anti-C1q was used in the second electrophoretic step. A diffuse precipitation arc was shown in the α region, which on further analysis was found to contain C1r, C1s and C1 inhibitor.

Crossed immunoelectrophoresis has been used to study C1 and C1 activation in various diseases with an immunological background. Figure 1 shows the findings with serum from a patient with chronic urticaria and angioedema. Electrophoresis was run with monospecific antisera against the C1 subcomponents and with Ca^{2+} present in the first step and with EDTA in the second step. Two separate precipitation arcs appeared at the application site, representing C1r and C1s of the native C1 complex. Two separate precipitation arcs appeared also in the β region, caused by C1r and C1s, which were present in the serum as a complex of 'free' C1r–C1s in zymogen form. The third precipitate appearing in the α region was caused by increased amounts of complexes between C1r–C1s and C1 inhibitor. Performance of both the electrophoretic steps in the presence of Ca^{2+} resulted in a depressed, 'filled' precipitation arc in the β region, indicating the dependence upon Ca^{2+} for the complexing between C1r and C1s.

Such patterns are often found in sera from patients with rheumatoid arthritis, systemic lupus erythematosus, chronic urticaria or primary biliary

Figure 1 Crossed immunoelectrophoresis of serum from a patient with chronic urticaria and angioedema. The separating electrophoretic step was done in the presence of Ca^{2+} , and the second electrophoretic step was performed with a mixture of anti-C1s and anti-C1r in the gel and with (A) EDTA or (B) Ca^{2+} in the buffer. cirrhosis. Sera from children with recurrent pneumococcal otitis media often contain excessively high levels of zymogen C1r–C1s complexes, which disappear on recovery.

By means of crossed immunoelectrophoresis, aberrations within the immunoglobulins can be visualized, thus revealing deficiency states or myeloma and macroglobulinemia, even though other methods are now available that are generally used for this purpose.

Crossed immunoelectrophoresis is very useful in complement research, making possible the analysis of the activation of the classical and alternative pathways. It is an important clinical tool for obtaining information on the involvement of complement in the pathogenesis of various immunological and inflammatory diseases.

Electrophoresis-immunofixation

With these techniques protein mixtures are separated by electrophoresis in agarose, polyacrylamide gels, on cellulose acetate strips or by isoelectric focusing, followed by overlaying with monospecific antiserum. After incubation and washing, the gel is stained for precipitated proteins. The method is used for phenotyping, for instance of the C4 complement component. It is also widely used for identification of the abnormal proteins in myeloma, Waldenström's macroglobulinemia and heavy and light chain diseases.

Electroimmunoassay (rocket immunoelectrophoresis)

When electrophoresis of an antigen is performed from a punched well in an agarose gel containing the corresponding antibody, a precipitate is obtained with a rocket-like appearance, the height of which is proportional to the amount of antigen in the gel. The shape of the precipitate is dependent on the antigenic content of the molecule studied and on the specificities of the antibody used in the agarose gel. Therefore, visual examination of the shape of the precipitate is very important and must be compared with the shape of the precipitate obtained with a standard preparation of the relevant antigen. Thus C1s rockets obtained with normal plasma are clear and distinct, whereas in many pathological sera diffuse precipitates are obtained, indicating changes in the antigenic reactivity of C1s, usually due to masking of antigenic determinants by complex formation with C1 inhibitor or by conformational changes during activation of C1. A similar course of events may be of relevance for several plasma proteins. Findings of aberrations by electroimmunoassay may provide

a basis for further analysis of, for example, complex formation, cleavage of the molecule or genetic antigenic variation.

Investigation of the C1 inhibitor by the rocket technique in a patient with hereditary angioedema using anti-C1 inhibitor in the gel showed a very high and thin precipitate, indicating a molecular structure partially different from that of normal C1 inhibitor (Figure 2). Further analysis showed that the nonfunctioning inhibitor of the patient was complexed with albumin. The high, rather thin rockets can be explained by masking of antigenic determinants on the C1 inhibitor molecule, resulting in fewer sites able to combine with the antibody.

The electroimmunoassay allows specific and quantitative determination of antigen in mixtures of proteins, such as serum, plasma, synovial fluid, urine, cerebrospinal fluid and so forth. It is an easy and fairly rapid method, taking between 2 and 16 hours, depending on the electrophoretic mobility of the molecules under investigation and the field strength used. Electroimmunoassay has been widely used for quantification, particularly of plasma constituents such as acute phase proteins (e.g. C-reactive protein (CRP), α_1 -antitrypsin, α -antichymotrypsin) and complement components (for diagnosing complement deficiency and hypo- or hypercomplementemia).

The electroimmunoassay is an easy and rapid laboratory method for tracing the individual proteins in chromatographic separation studies and possible changes in their structure during purification procedures. The morphology of the precipitate obtained is of importance in assessing any denaturation of the molecules under study. In this respect both electroim-

Figure 2 Rocket electrophoresis of C1 inhibitor in serum from a patient with hereditary angioedema. Anti-C1 inhibitor was present in the agarose gel. The four holes to the left contained normal serum in dilution 1/10, 1/20, 1/40, 1/80. The two holes to the right contained serum from the patient diluted 1/20.

munoassay and crossed immunoelectrophoresis may provide further information which complements results obtained with other techniques.

Modifications of electroimmunoprecipitation methods

Techniques using intermediate gels

The components of molecular complexes precipitating in the electroimmunoassay may be identified in greater detail by using an intermediate gel, cathodal to an anodal gel containing the discriminating antibody. Molecular complexes containing a component corresponding to the antibodies in the intermediate gel will be trapped there, resulting in smaller or no precipitates in the anodal gel, which contains the antibodies identifying the other molecular components of the complex. This variation of the electroimmunoassay and crossed immunoelectrophoresis has been often used, for example for the detection and measurement of C3d in plasma and synovial fluid ('double decker electrophoresis') (Figure 3). A cathodal intermediate gel incorporates antibodies which react with epitopes common to native C3, C3b and C3c, but absent in C3d. C3, C3b and C3c molecules are precipitated by anti-C3c and do not reach the anodal gel, which contains antibodies specific for C3d. C3d passes freely into the anodal gel and forms a precipitate with anti-C3d.

Figure 3 Rocket immunoelectrophoresis ('double decker electrophoresis') for quantitation of C3d. Samples were applied in holes in a cathodic gel containing antibodies reacting with C3, C3b and C3c, but not with C3d. Anodal to this gel, a gel with antibodies to C3d was moulded. The four holes to the left contained dilutions of normal serum treated with inulin to convert C3 to C3d.

A similar simplified procedure for trapping protein-protein complexes is obtained by filling a small basin – anodal and near to the antigen application well – with antibodies against one of the components of the complex under study. In electroimmunoassay the height of the rocket will be less than that of the rocket in a parallel run where the anodal basin contains buffer or an irrelevant antibody.

Fused rocket immunoelectrophoresis

This modification of the rocket technique can be utilized to visualize the distribution profile of individual proteins in mixtures, and has proved valuable in the analysis of fractions obtained in separation and purification experiments. The samples are applied to a row of wells in an antibody-free agarose gel, adjacent to an agarose section containing antibodies to the various proteins that may be present in the samples. After diffusion into the antibody-free gel, the proteins are induced by electrophoresis to migrate into the gel containing antibody. An undulating precipitation line will be formed showing the quantitative distribution of each antigen.

Tandem crossed electrophoresis

In this modification of crossed immunoelectrophoresis the first electrophoretic step is run with an antigen mixture applied in adjacent wells in the agarose gel, followed by electrophoresis into the second gel containing appropriate antibodies. The resulting precipitates help to reveal identity, partial identity and nonidentity between the proteins used in the experiment.

Further variants are line immunoelectrophoresis and rocket line immunoelectrophoresis, which have been used for comparing the antigenic composition of unknown proteins with mixtures of standard antigens.

Counterimmunoelectrophoresis or immunoelectro-osmophoresis

This method is utilized to accelerate and accentuate immunoprecipitation. Most antigens are negatively charged and move towards the anode in an electric field, whereas IgG immunoglobulins in buffers of pH 8.2–8.6 are fairly stationary owing to the electroendosmotic flow in the agarose matrix. The antigen is applied in a well at the cathodal end of the gel and the antibodies in a corresponding anodal well. On electrophoresis the antigen migrates towards the antibody, a precipitate being formed where they meet. The technique is widely used in microbiology for the detection of bacterial carbohydrate antigens, especially in cerebrospinal fluid, and for detection of

viral antigens in body fluids and in screening for viral antibodies.

Affinity electrophoretic method(s)

This procedure is used to study interactions between lectins and glycoproteins. The principle is the same as in immunoelectrophoresis using an intermediate gel containing antibody. However, instead of antibodies, lectins are incorporated into the intermediate gel and the second step is then performed in the usual way. Components binding to the lectin will be trapped in the intermediate gel and lower or no precipitation arcs will appear, as compared with the control experiment. This method and its variants allows identification of ligand-binding proteins and characterization of reactive sites.

Amplification methods

Sandwich technique using enzyme-labeled anti-Ig antibodies

After ordinary performance of crossed immunoelectrophoresis or electroimmunoassay, the gel is pressed, washed and then overlaid and incubated with enzyme-labeled anti-Ig antibodies directed against the antibodies used in the agarose gel. After washing, the precipitates in the gel are visualized by staining with the substrate of the enzyme label on the anti-Ig. As compared with protein staining with Coomassie brilliant blue, there is a 25–50 fold increase in sensitivity. This method is of value in studies of plasma proteins present at low concentrations. Factor D of the alternative pathway of complement, with an average plasma concentration of 1.6 mg l^{-1} can be determined by this sandwich variant of electroimmunoassay, and its relationship to and reactivity with other plasma components can be studied.

Radioimmuno-electrophoresis

The sensitivity of crossed immunoelectrophoresis and of rocket immunoelectrophoresis can be increased by the addition of radiolabeled anti-Ig antibodies after completion of the electrophoresis, as described above for enzymatic amplification of the methods. After washing of the gel, the radiolabeled anti-Ig antibodies will bind to the trace immunoprecipitates present in the gel. With autoradiography the precipitation lines can be determined. The method has been used for identification of allergens and determination of the specificity of patients' IgE.

A rocket electrophoresis variant consists of incorporation of a radiolabeled antigen in an antibody-free gel section at the site of sample application.

Adjacent to this section, the gel containing the relevant antibodies is moulded. As with the enzyme-labeled methods, the techniques using radiolabeled antigens in the gel have been used for the study of proteins present at low concentrations in body fluids. Examples include α -fetoprotein and certain pregnancy-associated proteins such as chorionic gonadotropin.

Electrofocusing-immunoelectrophoresis

The isoelectrophoretic separation of protein mixtures – most commonly by polyacrylamide electrophoresis – is followed by electrophoresis in a gel containing antibody. Thus the proteins can be characterized by their isoelectric point and the antigenic composition can be determined. This gives high resolution of identity, partial identity and nonidentity of various antigens, of genetic variants of single antigens, and of isoenzymes.

Electroimmunoprecipitation and electroimmunofocusing are also suitable for analysis of solubilized membrane proteins. For example the terminal C5b–C9 complement complex was studied and could be shown to be integrated in the erythrocyte membrane. Analysis by these methods of membranes of lymphocytes and thrombocytes as well as of membranes of microorganisms have proved valuable in the study of membrane proteins.

IMMUNOGEN

Michael Sela, Department of Chemical Immunology, The Weizmann Institute of Science, Rehovot, Israel

Immunogen is a substance (molecule) capable of provoking an immune response. This immune response may be strictly cellular, leading to a specific T cell response, or it may lead to specific antibody formation. The notion of immunogen should be distinguished from that of *antigen*, which encompasses both the properties of an immunogen but also that of a substance which cross-reacts immunospecifically with antibodies or immunocytes but is incapable of triggering an immune response. It should also be distinguished from a *tolerogen*, which is a substance (molecule) inducing immunological tolerance.

Immunogenicity is the capacity to provoke an immune response. When one refers to an immunogenic molecule, this means that this molecule is capable of triggering an immune response by itself, not when conjugated to another macromolecule. Thus, an immunogenic peptide, for example, refers to a peptide immunogenic by itself, whereas a peptide which serves as an important epitope while attached to a macromolecule, should be referred to as *immunopotent* or, if it is more immunopotent than related peptides, as *immunodominant*.

A chemical or physical change in a molecule that will result in an increased immune response will increase its immunogenicity, even though it may or may not have changed its *antigenic specificity*.

The immunogenicity of a substance will depend on the manner in which it is administered, on the amount administered, and on the genetic make-up of the animal or human being immunized. Defining a substance as immunogenic will depend on the sensitivity of the method used to detect the immune response.

IMMUNOGLOBULIN, CELL SURFACE

John G Monroe, Department of Pathology and Laboratory Medicine, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

It was Ehrlich in 1900 who first postulated that lymphocytes recognized antigen via receptors on their cell surface which were structurally similar to the effector molecules that they secreted. This notion was later developed by Burnet into the clonal selection theory to account for specificity of the inductive and effector phases of the immune response. Subsequently, immunofluorescence studies by Coon and Möller established that B lymphocytes expressed immunoglobulin (Ig) molecules on their surface (sIg). This observation was quickly followed by the findings that these molecules were the antigen recognition structure, or antigen receptor, on the B lymphocyte.

Since these initial observations, all immunoglobulin isotypes have been found on the surface of individual B cells. In general, a given B lymphocyte expresses immunoglobulin of only one isotype at any given time. The exception to this rule are unstimulated, mature B lymphocytes which coexpress surface IgM (sIgM), as well as surface IgD (sIgD).

Function of surface immunoglobulin

Membrane-associated immunoglobulin functions as a receptor on the surface of B cells which recognizes and binds antigen. Upon binding antigen, the sIg-antigen complex is endocytosed, processed and represented on the B cell surface in association with class II major histocompatibility antigens (MHC class II) for presentation to class II-restricted T helper cells. This interaction serves to facilitate activation of the T cell, which in turn delivers activation and differentiation signals to the B cell. In fact, it has been argued that the only signals necessary for B cell activation are derived from this B-T cell interaction; sIg, in this case, plays an insignificant role in generating activation signals for the B cell. In this regard, antigen processing and presentation by B cells has been found to be independent of sIg signaling. Monovalent immunoglobulin-specific antibodies (anti-Ig) that would not be expected to elicit an activation signal because they do not cross-link the receptor, nonetheless are presented as efficiently as divalent anti-Ig to Ig-specific T cell lines. This interaction generates the necessary signals for the activation of the T cell, which in turn can provide all the required signals for stimulation of the B cell to proliferate and secrete immunoglobulin. In an apparent contradic-

tion of this conclusion, other studies clearly establish that signals generated by sIg cross-linking do potentiate the activation of the B cell. In fact, under conditions of optimal antigen receptor cross-linking (i.e. by divalent anti-Ig or thymus-independent antigens) these signals are sufficient to trigger entry into cell cycle and proliferation by the B cell.

To reconcile these apparently contradictory requirements for triggering B cells, it is perhaps informative to consider that antigen-specific activation of the B cell requires that the B cell achieve a certain threshold stimulation. Superoptimal T cell help and sIg cross-linking are by themselves each able to facilitate at least the initial stages of B cell activation. However, in most cases, the initial sIg signal is suboptimal and the antigen-reactive T helper cells at the time of initial interaction with the B cell are not optimally activated. In this more typical case, multiple signals generated through sIg and as a consequence of B cell presentation of antigen to the T cell are necessary to achieve activation. This idea is consistent with the observation that sIg-stimulated B cells express higher levels of class II antigen and surface molecules involved in costimulation of T helper cells.

Structure and composition of the B cell antigen receptor (BCR)

The basic monomeric structure of sIg is identical to that of the secreted form of this molecule. Each molecule possesses two light chains disulfide coupled to two disulfide-linked heavy chain molecules. The membrane form of immunoglobulin differs from the secreted form with respect to the carboxy end of the molecule. The membrane form includes additional amino acid residues comprising a spacer, transmembrane and cytoplasmic region. This material is encoded by two additional exons, M1 and M2, which differ to a greater or lesser extent for each immunoglobulin. Production of the membrane form as opposed to the secreted form is determined post-transcriptionally through differential RNA processing.

The basic structure of the membrane form of sIgM is illustrated in **Figure 1**. The spacer region is composed of 12 residues. This region is highly hydrophobic, containing six glutamic acid residues per chain. The spacer region is followed by a highly con-

Figure 1 Structure of membrane-associated IgM. Shaded amino acid residues depict those of high variability between immunoglobulin isotypes. General structure and postulate stoichiometry of Ig- α and Ig- β molecules highlighting ITAMs.

served hydrophobic sequence of 25 amino acids which comprises the transmembrane region. Homology within this region is high among different iso-types, with differences tending to cluster to specific subregions. Interestingly, imposition of an α -helical configuration to the transmembrane region clusters these nonhomologous residues to the outside of the structure, leaving the most highly conserved residues at the point of interaction between the two heavy chains.

The C-terminal segment of the molecule is hydrophilic, beginning with lysine-valine-lysine for μ , δ , and γ . This sequence constitutes the entirety of the cytoplasmic domain for μ and δ . The γ isotypes possess an additional 25 amino acids. The membrane form of the α isotype does not contain the characteristic lysine-valine-lysine cytoplasmic sequence but, rather, possesses a unique 14 amino acid stretch.

The BCR exists as a complex in the plasma membrane of the B cell, consisting of the slg antigen recognition structure together with the Ig- α (CD79a) and Ig- β (CD79b) proteins. These latter molecules are products of the mb-1 and B29 genes, respectively, and constitute the signaling components of the B cell antigen receptor. Both the Ig- α and Ig- β proteins possess extensive cytoplasmic domains which contain a region called an immunoreceptor tyrosine-based activation motif (ITAM) homologous to other signaling molecules in the immune system, including components of the T cell antigen receptor. Tyrosine residues associated with these ITAMs become phosphorylated following slg cross-linking and are important in initiating biochemical signaling pathways associated with antigen-driven B cell activation.

slg transmembrane signaling

Cross-linking sIg causes a rapid activation of receptor-associated tyrosine kinases. These kinases, *fyn*, *lyn*, *blk*, and in some reports *lck* belong to the *src* family of tyrosine kinases and are associated with the receptor in the unstimulated B cell. It is currently believed, although not formally proven, that these receptor-associated kinases are responsible for the tyrosine phosphorylation of the ITAMs of Ig- α and Ig- β described above, as well as a number of other protein substrates responsible for initiating defined biochemical signaling pathways associated with sIg-induced activation. These substrates and signaling pathways are shown in Figure 2. So far, three signaling pathways have been shown to be associated with BCR signal transduction: phosphatidylinositol (PI) hydrolysis, *ras*/MAPK and phosphatidylinositol-3-kinase (PI3K) pathways. Association with multiple signaling pathways might at first be unexpected but probably reflects the fact that antigen stimulation through sIg must initiate a number of diverse cellular responses (i.e. ligand internalization and processing, changes in cell adhesion and localization, proliferation, differentiation). Regulation of these pathways is complex and there is evidence for cross-talk occurring between them.

Phosphatidylinositol hydrolysis (PI hydrolysis) has been shown to be important in linking BCR signaling to cell cycle entry and proliferation. Phospholipase C (PLC)-catalyzed hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP₂) results in the generation of diacylglycerol (DAG) and inositol triphosphate (IP₃), which activate the serine/threonine kinase PKC and cause a release of calcium from stores in the endoplasmic reticulum, respectively. Protein kinase C (PKC) and Ca²⁺ act as intracellular second messengers to propagate the BCR-generated signals through

Figure 2 Signal transduction pathways associated with slg in mature-stage B cells. See text and references for details.

the cytoplasm. As demonstrated first in the platelet-derived growth factor receptor system and later in B cells, tyrosine phosphorylation of PLC γ 1 and γ 2 is necessary for the receptor-induced activation of their enzymatic activity. Therefore, the BCR-induced tyrosine phosphorylation of PLC γ 1 and γ 2 observed in B cells is likely to be an important event linking slg cross-linking to downstream signaling events. Furthermore, PI-pathway linked activation of PKC may be involved in the regulation of other signaling pathways in B cells. Through its ability to activate *vav* and SOS, PKC may be involved in regulating the activation of p21^{ras}.

p21^{ras} is a membrane-associated guanine nucleotide-binding protein whose activation has been as-

sociated with receptor-mediated activation in a number of cell types, in addition to BCR-stimulated B cells. The regulation of *ras* during receptor signaling is complex, involving a number of cytoplasmic signaling processes. Positive activation of *ras* in BCR-stimulated B cells has been shown to involve the sequential recruitment of shc, grb2 and the guanine nucleotide exchange factor SOS to the phosphorylated ITAMs of the Ig- α and Ig- β chains of the BCR. Recruitment of SOS facilitates the exchange of GTP for GDP at the nucleotide-binding pocket of *ras*, resulting in a catalytically active molecule. Negative regulators of *ras* activity also exist. Evidence argues that GAP, another substrate of tyrosine kinases in B cells, reduces activity of *ras*, a regulatory process that

is reversed upon tyrosine phosphorylation of GAP. Although a target for tyrosine kinases in B cells, the limited experimental evidence available does not support a role for GAP in the regulation of *ras* in BCR-stimulated B cells. However, another GAP-like protein, neurofibromin, may play a role. Finally, PKC has also been shown to upregulate *ras* activity, although the mechanism by which this regulation is accomplished is not fully understood.

Recently, it has been observed that PKC may activate *vav*, and *vav* has been shown to be able to affect *ras* activation, presumably due to its ability to accelerate the GDP–GTP exchange associated with the activation of *ras*. Thus, the *ras* signaling pathway can be directly activated by tyrosine kinase activation (in the case of *shc/grb2/SOS*) as well as indirectly by the PI-hydrolysis pathway (in the case of PKC activation of *vav*), demonstrating both the redundancy inherent in many signal transduction pathways as well as the cross-talk that can occur between different second messenger pathways.

The PI3K pathway is the most poorly understood signaling pathway associated with BCR signaling. Phosphorylation and activation of PI3K has been shown to occur following BCR cross-linking. The target of PI3K is the phospholipid PIP₂, which is phosphorylated to PIP₃. The relevance of PIP₃ in signal transduction is not well-defined, although it has been implicated in the activation of the nonconventional protein kinase C isozyme, PKC ζ . In *Xenopus*, PKC ζ has been implicated in oocyte maturation and in responses to the PDGF receptor in fibroblasts. However, the role of PKC ζ and the PI3K pathway has not been studied in BCR-stimulated B cells.

Developmental regulation of BCR signaling

Immunoglobulin heavy chain genes are rearranged and expressed during the late pro-B cell stage. Recently it has been shown that these are expressed on the surface of pre-B cells. However, in contrast to mature-stage B cells the pre-B cell form of sIg is not associated with the conventional κ or λ light chains. Rather, the μ heavy chain is complexed with the $\lambda 5$ and VpreB proteins which form the surrogate

light chain. The $\mu\lambda 5$ /VpreB complex, like the mature form of the antigen receptor, is associated with Ig- α and Ig- β and there is some preliminary biochemical and functional evidence to suggest that it generates a signal. The ligand for the pre-B cell form of sIg and the role of this receptor in B cell biology is under investigation.

The mature form of sIg is first expressed at the immature stage of B cell development. Interestingly, while cross-linking sIg on mature, immunocompetent B cells initiates activation, sIg cross-linking on immature-stage B cells leads to negative selection and tolerance. Although there are a number of possibilities that could account for differences in complex processes involving activation and tolerance induction of B cells, there is evidence to suggest that the mechanism of sIg signal transduction in immature and mature B is different.

IMMUNOGLOBULIN CLASS SWITCHING

Jürgen Schmitz, Miltenyi Biotec, Bergisch Gladbach, Germany

Andreas Radbruch, Deutsches Rheuma-Forschungszentrum Berlin, Berlin, Germany

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The class of an antibody determines its functional properties and thus the kind of humoral immune response against a particular antigen. In 1964, Nossal and collaborators observed for the first time that individual B cells can switch the class of the immunoglobulin (Ig) they produce, while retaining the antigenic specificity. The molecular basis for this process, termed isotype or class switching, is a recombination between highly recombinogenic DNA sequences, so-called switch (S) regions. The switch recombination machinery is induced in naive and memory B cells upon activation by antigen or mitogen and targeted to distinct S regions by cytokines. These cytokines target recombination to particular S regions by inducing transcription of the respective S regions prior to recombination and this transcription is somehow functionally linked to the recombination event.

Molecular basis of immunoglobulin class switching

Mice have antibodies of the classes IgM, IgD, IgG3, IgG1, IgG2b, IgG2a, IgE and IgA, and humans of the classes IgM, IgD, IgG3, IgG1, IgG2, IgG4, IgE, IgA1 and IgA2. Antibody classes differ in the Ig heavy chain constant region gene (C_H gene) that is expressed. The C_H genes are clustered at the 3' end of the Ig heavy chain variable region genes (V_H genes). The entire murine C_H gene locus spans approximately 200 kb with eight C_H genes that are arranged in the order 5' C_{μ} - C_{δ} - $C_{\gamma 3}$ - $C_{\gamma 1}$ - $C_{\gamma 2b}$ - $C_{\gamma 2a}$ - C_{ϵ} - C_{α} 3'. The human C_H gene locus extends over more than 300 kb with nine functional genes and two pseudogenes (ψ) that are ordered 5' C_{μ} - C_{δ} - $C_{\gamma 3}$ - $C_{\gamma 1}$ - ψ_{ϵ} - $C_{\alpha 1}$ - ψ_{γ} - $C_{\gamma 2}$ - $C_{\gamma 4}$ - C_{ϵ} - $C_{\alpha 2}$ 3'.

Coexpression of C_{μ} and C_{δ} with the same VDJ gene on mature naive IgM⁺ IgD⁺ B cells is due to differential termination of transcription and differential splicing of transcripts encompassing both constant region genes.

The molecular basis of antibody class switching to the expression of C_{γ} , C_{ϵ} , and C_{α} genes in activated B cells is a recombination which positions the new C_H gene 3' next to the VDJ gene. The apparent sites of Ig class switch recombination are located within the S regions, highly repetitive DNA sequences which are present 5' of each C_H gene, except C_{δ} .

All murine and most humans S regions are sequenced at least partially. They are 1–10 kb in length, highly repetitive and GC-rich. Murine and human S_{μ} are almost homogeneously composed of the two pentamer sequences GAGCT and GGGGT and the heptamer sequence (C/T)AGGTTG. All other S regions also contain multiple copies of the pentameric sequences. All murine S regions except S_{μ} are composed of tandem repeats that vary both in sequence and in length, with 49 bp repeats for $S_{\gamma 1}$, $S_{\gamma 3}$ and $S_{\gamma 2b}$, 52 bp repeats for $S_{\gamma 2a}$, 80 bp repeats for S_{α} and 40 bp repeats for S_{ϵ} . Both human and murine S_{μ} are more homologous to S_{ϵ} and S_{α} than to the S_{γ} regions, which have considerable homology among each other. The homology of murine S_{γ} regions to S_{μ} decreases with the distance on the chromosome ($S_{\gamma 3} > S_{\gamma 1} > S_{\gamma 2b} > S_{\gamma 2a}$). The S regions are sufficiently conserved between human and mouse to allow human S regions to be used as substrate for switch recombination in murine cells. The S_{μ} , S_{ϵ} and S_{α} regions are more homologous between the two species than the S_{γ} regions. The length of the S regions is subject to considerable allelic variation (length polymorphism) indicating that there is no functional requirement for a particular size of a given S region.

S regions are preferred targets not only for the switch recombination machinery but also for other bacterial and eukaryotic recombination systems. The extraordinary recombinogenic potential might be due, in part, to the formation of unusual DNA structures promoted by the repetitive character, the high degree of homology and the high GC content of S regions.

The primary mechanism for switching that relocates a new C_H gene next to the VDJ gene is an intrachromosomal recombination between a donor and an acceptor S region, with looping out and deletion of the intervening DNA as a circle, that can be isolated from switched cells. In rare cases the deleted DNA is reintegrated in inverted form either back into the C_H gene locus or even into other regions of the genome.

More than 150 DNA sequences at S region recombination sites have been analyzed. Within S regions, switch recombination breakpoints are evenly distributed, without apparent preference of a particular area within the S region and without specific signal

sequences present at or juxtaposed to all switch recombination sites. Some recombination sites reveal a few base pairs of homology between donor and acceptor S region. Analyzing switch recombination sites is difficult and results have to be taken with care due to the possibility that during amplification and cloning of recombined switch sequences, additional recombinations might take place in bacteria used for cloning and the sites identified may be not the sites of the primary switch recombination event in B cells.

Mitotic switch recombination by unequal crossing-over between sister chromatids may occur occasionally. It results in the asymmetric segregation of C_{H1} genes, giving rise to one daughter cell with a deletion of C_{H1} genes and another with a duplication.

Switch recombinations normally occur in *cis*, but S regions can also be recombined in *trans*. This has been demonstrated in several B cell lines, for normal B cells of transgenic mice with an additional S_{μ} region integrated outside the C_H gene locus, and at a surprisingly high frequency for rabbit B cells. Transchromosomal recombination is also responsible for some *c-myc* gene translocations, in which only one of the recombination partners is an S region.

Coexpression of IgM along with IgG, IgA or IgE on the surface, with all C_{H1} genes still in germline configuration, has been reported in both normal and transformed B cells. However, in most cases it has not been ruled out that Ig of one of the classes had been passively picked up, e.g. by class-specific Fc receptors. If cells expressing IgM together with other, non-IgD isotypes exist, they might do so either by differential processing of long transcripts spanning the VDJ, C_{μ} , C_{γ} , C_{α} and C_{ϵ} genes or by trans-splicing of the VDJ exon from primary VDJ- C_{μ} transcripts to C_{γ} , C_{α} or C_{ϵ} exons from C_{γ} , C_{α} or C_{ϵ} switch transcripts (see below). Both models have been proposed, but so far clear evidence showing that either or both of them are of biological relevance has not yet been provided. Instead, it has been shown that surface IgA1-bearing B lymphocytes from human peripheral blood, i.e. IgA1⁺ memory B cells, express only IgA1 and have already performed switch recombination, as seen in IgA-secreting plasma cells. This leaves little room for a physiological role of Ig class switching without switch recombination, except for IgD expression.

Induction of switch recombination

The switch recombination machinery can be induced in naive IgM- and IgD-expressing B cells and in memory B cells *in vitro*, by cross-linking surface Ig with mimics of T cell-independent type 2 (TI-2

antigens) such as anti-Ig antibody conjugated to dextran, by B cell mitogens (TI-1 antigens) such as bacterial lipopolysaccharide (LPS), or by activated T cells. Triggering of CD40 on B cells by its ligand (CD40L) on activated T cells, appears to play a crucial role for switch induction in the process of T cell-dependent B cell activation. Point mutations or deletions in the gene encoding the CD40L are responsible for the X-linked hyper-IgM syndrome, which is characterized by dramatically reduced levels of serum Ig of classes other than IgM, reflecting a severe defect in T cell-dependent immune responses and Ig class switching. Similarly, CD40- and CD40L-deficient mice show normal IgM but no detectable IgG, IgE and IgA antibody responses to T cell-dependent antigens, while antibody responses to type II T cell-independent antigens are not affected.

Within a period of about 2 days after onset of B cell stimulation, activated B cells begin to undergo class switching at high frequency. Frequencies of switched cells can be as high as 10% per generation. Switch recombination is not necessarily a one-hit event in individual cells. Usually activated B cells undergo switch recombination not only on the expressed but also on the allelically excluded IgH allele.

Intra-S region recombinations can also occur in switching cells, especially involving sequences in the area of the S_{μ} pentameric repeats and 5' thereof, which are frequently deleted on the chromosome after the switch recombination between two different S regions has taken place. Intra-S region recombinations are also observed on S regions of non-switched excluded IgH alleles, in particular on S_{μ} , and on downstream S regions, the latter in the case of S_{μ} -inactivated cells. Secondary or even tertiary switches involving two or more S regions downstream of S_{μ} on the chromosome can also occur, allowing B cells to switch sequentially to different isotypes. This seems to be the dominant although not obligatory pathway for switching to IgE, which often occurs via IgG1 in mice or IgG4 in humans.

All switch recombinations inducing B cell differentiation signals also induce DNA synthesis and proliferation in resting B cells, but it is not clear whether replication of DNA is required for switch recombination. Several groups have reported evidence that DNA synthesis is associated with switch recombination since inhibition of DNA synthesis in B cells also inhibits switching. Small mutations (substitutions, insertions and deletions), indicative of error-prone DNA synthesis, have been identified near the sites of switch recombination.

In hybrid cells of class switch-performing activated B cell blasts and immortalized plasma cells, switch

recombination is arrested indicating that the switch recombination machinery may be actively turned off by an inhibitor in the plasma cell stage.

Directing switch recombination to distinct switch regions

The choice of the S regions involved in class switch recombination in individual cells is not random. This first became evident from the observation that switch recombinations involving S regions of the same class of Ig occur on both IgH alleles of individual switched cells. Since those B cells could hardly have been selected for a particular switch recombination on a non-expressed IgH allele, this analysis has shown that activated B cells expressing particular isotypes are committed to switch to particular classes of Ig.

When and how is this commitment induced? It is clear that, depending on the mode of activation of the B cell and dependent on cytokines produced by T cells or other cells, including natural killer (NK) cells, mast cells, basophils and macrophages, distinct S regions are targeted for recombination in activated B cells. In the mouse, three cytokines, interleukin 4 (IL-4), interferon γ (IFN γ), and transforming growth factor β (TGF β), have been shown to play pivotal roles in this process; others may be identified in the future. IL-4 targets the S $_{\gamma 1}$ and, at higher concentrations, also the S $_{\epsilon}$ region for switch recombination, IFN γ targets the S $_{\gamma 3}$ and S $_{\gamma 2a}$ regions for switch recombination, and TGF β targets the S $_{\gamma 2b}$ and S $_{\alpha}$ regions for switching. Thus, each of the three cytokines regulates two of the six non-IgM, non-IgD murine Ig isotypes in a positive manner. Furthermore, in the mouse, IFN γ suppresses IL-4-induced switching to IgG1 and IgE, while IL-4 suppresses IFN γ -induced switching to IgG3 and IgG2b. Neither IL-4 nor IFN γ are obligatory for switch induction. IFN γ receptor-deficient mice can still produce IgG3 and IgG2b, and IL-4-deficient mice can still produce IgG1, albeit in reduced amounts. For human B cells, less is known about the signals that induce or suppress certain S regions for recombination, except that both IL-4 and IL-13 target the S $_{\gamma 4}$ and S $_{\epsilon}$ regions for switch recombination, probably by signaling via a shared receptor component of the IL-4 and IL-13 receptors.

At the molecular level, targeting of certain S regions for switch recombination is strictly correlated with induction of transcription of those S regions. This has been well established for cell lines which are stably committed to switch to particular Ig isotypes, as well as for murine and human B cells stimulated by switch-targeting cytokines. Human and murine S region transcripts (switch transcripts)

initiate at multiple initiation sites of a promoter, the I $_{\text{H}}$ promoter, located upstream of the respective S region, proceed through the S region and terminate at the normal polyadenylation sites downstream of the respective C $_{\text{H}}$ gene. The primary transcripts are processed into mature switch transcripts and transported into the cytosol. The processed switch transcripts, also called 'sterile' or 'germline' transcripts, differ from the productive VDJ C $_{\text{H}}$ mRNAs by an exon, the I $_{\text{H}}$ exon, encoded just 5' of the S region that, instead of the VDJ exon, is spliced to the first C $_{\text{H}}$ exon. Although transcription from the V $_{\text{H}}$ promoter proceeds through the S $_{\mu}$ region after VDJ recombination, in addition switch transcripts containing an I $_{\mu}$ exon initiate from the I $_{\mu}$ promoter. After switch recombination, transcription from this I $_{\mu}$ promoter proceeds through the hybrid S region and hybrid switch transcripts containing the I $_{\mu}$ exon and the exons of the switched C $_{\text{H}}$ gene are generated. Transcription of hybrid S regions might be required for sequential switching to downstream isotypes. Due to stop codons in the I $_{\text{H}}$ exons, switch transcripts are not translated into proteins (i.e. they are sterile). At most, short sequences may be translated into peptides.

The functional dependency of switch recombination on S region transcription has been effectively demonstrated by targeted deletion or replacement in murine genomes of the I $_{\gamma 1}$ and I $_{\gamma 2b}$ exons together with their cytokine-responsive promoters, which results in an almost complete and selective deficiency in germline transcription of the adjacent S regions as well as switch recombination to S $_{\gamma 1}$ and S $_{\gamma 2b}$, respectively. Deletion of the J $_{\text{H}}$ gene segments and the I $_{\mu}$ promoter leads to a drastic reduction of switch recombination involving S $_{\mu}$.

Along with transcription of S regions, cytokines such as IL-4 have also been shown to induce selective hypomethylation of previously hypermethylated CpG dinucleotides and to induce DNAase I hypersensitive sites at the regions of initiation of germline transcription. In general, induction of demethylation and of DNAase I hypersensitivity has been shown to reflect binding of inducible transcription factors to promoter and/or enhancer DNA sequences. Identification and characterization of the cytokine-responsive transcription elements that control S region transcription and cloning of the cytokine-inducible nuclear transcription factors that bind to these elements is just in its infancy. At present most information is available on the murine I $_{\epsilon}$ promoter. A minimal 179 bp I $_{\epsilon}$ promoter sequence was shown to impart IL-4-inducible and IFN γ -suppressive transcription to a heterologous reporter gene. Using electrophoretic mobility shift assays (EMSA), several

nuclear protein complexes have been demonstrated to bind to this region, but only two of the proteins involved have been cloned so far, STAT6 (STF-IL4) and BSAP. STAT6 is a member of the signal transducer and activator of transcription family of proteins that is activated by tyrosine phosphorylation in response to IL-4. STAT6-null mice are deficient in class switching to IgE. BSAP, also referred to as α -BP or NF- κ B1, is an early B cell lineage-specific activator protein which binds to an indispensable DNA element of the I ϵ promoter, but also to several other regions within the murine IgH locus, including sites 5' of the S α and S γ 2a region, repetitive sequence

motifs of the S μ region and sequences within the Ig 3' C α enhancer.

Molecular components of the switch recombinase

So far, efforts to identify components of the switch recombinase have focused on S region-binding proteins. A few such proteins such as LR1 and NF κ B or SNUP, SNAP and SNIP have been cloned, but so far no functional role in switch recombination could be attributed to any of them unequivocally (Figure 1).

An interesting observation is that transcription of

Figure 1 Mechanism of class-switch recombination.

S regions as such is insufficient to target switch recombination to particular S regions. Replacing the entire sequence of the I_ε exon together with its IL-4-inducible promoter by sequences of the IgH intron enhancer and a V_H promoter, substantial transcription through the S_ε region, but very little switch recombination to S_ε, is induced by LPS. Even more drastically, replacement of the I_γ1 promoter together with the entire I_γ1 exon by a human metallothionein (hMT) promoter completely shuts down switch recombination of S_γ1, although the S_γ1 region is constitutively transcribed. However, replacement of the I_γ1 promoter with the hMT promoter, leaving the splice donor site of the I_γ1 exon intact, targets switch recombination to S_γ1 at high frequency. These results strongly suggest that the process of splicing of switch transcripts, the spliced intron with S region sequences, or the spliced switch transcript play a functional role in targeting of switch recombination. Indeed, the primary switch transcripts or their splice products are obvious candidates for a class-specific component of the switch recombinase.

IMMUNOGLOBULIN, EVOLUTION OF

John J Marchalonis, Department of Microbiology and Immunology,
College of Medicine, University of Arizona, Arizona, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The first studies of antibody production in lower vertebrates were carried out between 1897 and 1903 by Mechnikoff, and Widal and Sicard in Europe and Noguchi in the USA. Mechnikoff emphasized the importance of comparative studies, showing that alligators produced antitoxins. Widal and Sicard showed that frogs made antibodies in response to inoculation with living typhus bacteria. Noguchi reported that turtles produced antibodies following challenge with whole blood from frogs, fish or other turtles. Studies of lower animals were carried out sporadically during the next 50 years, but there was a burst of interest in evolutionary studies in the 1960s. Good and his collaborators studied antibody production in nonmammalian vertebrate species ranging from cyclostomes to birds. In 1965, Marchalonis and Edelman first isolated and partially characterized immunoglobulins of a primitive vertebrate, the dogfish shark. They found that shark antibodies resembled mammalian immunoglobulins in possessing light and heavy polypeptide chains expressing charge diversity. Shark immunoglobulin most closely resembled mammalian IgM. Similar results were obtained for another shark, the lemon shark, by Clem and Small in 1967.

Although the fundamental similarities between immunoglobulin chains of lower vertebrates and their homologs in mammals was strongly indicated by the studies carried out in the late 1960s and early 1970s, definitive characterization of these molecules only became possible more recently. Initial strides in studies of immunoglobulins and their genes in human and mouse were facilitated by the fact that these mammalian species are subject to multiple myeloma, a cancer of the lymphoid system that results in the elaboration of monoclonal lymphocytes or plasma cells that secrete monoclonal immunoglobulins. No comparable monoclonal gammopathies occurred in primitive vertebrates. Therefore, the application of recombinant DNA technology which allowed genes to be cloned, sequenced and analyzed for their arrangements catalyzed a breakthrough in this area. Litman and his associates found that a murine V_H probe (S107) could be used to screen genomic libraries of elasmobranchs and reptiles with the detection and subsequent characterization of V_H genes showing greater than 60% identity to the mammalian prototype. In other instances, as in the

case of light chains of sharks, heterologous mammalian probes did not allow isolation of homologous genes and it was necessary to use the approach of isolating the shark immunoglobulins, making potent antiserum to them, and using these to screen cDNA libraries packaged in expression vectors. This approach was successfully used by Shambloott and Litman and Schluter and colleagues to obtain sequences of light chains of horned shark and sandbar shark respectively. Overall, there has been an explosion of knowledge regarding sequences and arrangements of immunoglobulin genes of lower vertebrates. Exciting work characterizing heavy chain genes of amphibians, teleosts and elasmobranchs by the above workers and others including Steiner, Du Pasquier, Schwager, Warr and Cuchens is currently being reported with increasing frequency. A fascinating development that emerged is that, despite the clear and strong homology in comparison among the corresponding chains of lower vertebrates and mammals, gene arrangements can vary considerably when the system specifying the homologous molecules are compared among sharks, chickens and mammals.

Immunoglobulin classes of vertebrates

All vertebrates can make antibodies that exhibit classic immunoglobulin structure consisting of two types of polypeptide chains that are polydisperse in charge and are usually linked covalently by disulfide bonds. Gene and protein sequence data are now available for immunoglobulins of all classes of vertebrates derived from the primitive jawed fish, the placoderms. These include elasmobranchs (e.g. sharks and rays), the ancestors of which diverged from those of mammals more than 400 million years ago, as well as teleost fish (e.g. goldfish), amphibians (e.g. bullfrogs and *Xenopus*), reptiles (e.g. the caiman), and birds (e.g. chickens). Based upon general structural properties, all placoderm-derived vertebrates possess antibodies comparable to the IgM (immune macroglobulin) isotype of mammals. The heavy chains are the same size as mammalian μ chains (70 kDa) and serological cross-reactions between the mammalian and shark chains have been found. The antibody molecules of sharks occur in two forms in serum: a 7S 'monomer' consisting of two light and two heavy chains of the form $(L\mu)_2$ and a pentamer of the form $(L\mu)_{10}$ comparable to the

predominant form of human IgM. The intact IgM molecules of bony fish teleosts occur in serum as tetramers instead of the pentamers found in other vertebrates.

Table 1 compares sequence alignments of the μ chains of horned shark, clawed toad, chicken and human. Overall, the sequence identity in the constant region domains is approximately 30%. The identity in the framework sequences of the variable regions ranges from 40 to 75%, illustrating strong evolutionary conservation of this portion of the molecule.

Other classes of immunoglobulin characterized by distinct heavy chains are present in lungfish (Dipnoi), amphibians, reptiles and birds. These resemble γ chains in consisting of multiple C-region domains, but are distinct from IgG immunoglobulins. All mammals, eutherians, marsupials and monotremes have 7S antibodies (apparent mass 150 000) having heavy chains of mass 50 000 that are serologically cross-reactive with human IgG. The distinct immunoglobulin monomers of amphibians, reptiles and birds have larger heavy chains than the mammalian γ chain and most probably represent the

products of heavy chain gene duplications distinct from the one which generated the γ chain. These non-IgM immunoglobulins have been termed IgY (amphibians, reptiles, chickens). In addition, other distinct immunoglobulin classes have been found in amphibians (IgX), lungfish (IgN, intact mass 120 000; heavy chain 40 000), reptiles (IgN in the turtle) and birds (IgN in the duck). These distributions are listed in Table 2.

Evolution of light chains

Light chains of mammals are classed as either κ or λ chains and their relative frequencies vary from species to species, e.g. in humans the ratio of κ to λ is 2 : 1, in the mouse it is 95% κ , 5% λ , and in pigs it is 5% κ , 95% λ . Comparison of gene and protein sequence data shows that the distinction between κ and λ chains is a phylogenetically ancient one that was established by the divergence between the ancestors of sharks and man. Table 3 compares the sequences of a light chain (cl 5.1) cloned from the sandbar shark (*Carcharhinus plumbeus*) with those of the characterized human λ Bence Jones protein Mcg, the mouse (MOPC 315) and the chicken. In many comparisons with mammalian λ chains, the C regions of the sandbar shark light chains characterized (six independent clones) show approximately 40% identity to the human, V regions >50% identity, and FR4 (encoded by the J or joining segment) about 75%. Figure 1 is a dendrogram depicting the evolution of light chain constant regions. The constant region of chicken light chains assorts with λ chain and that of the bullfrog clusters with κ chains.

Figure 1 Phylogenetic tree for immunoglobulin light chains derived from analysis of constant region sequences using the method of Feng and Doolittle (*Journal of Molecular Biology* 1987; 25: 351–360).

Comparative arrangement of immunoglobulin genes

Although light chains and heavy chains of placoderm-derived vertebrates (gnathostomes) are clearly homologous to one another and are specified by variable (V), diversity (D in heavy chains), joining (J) and constant (C) gene segments, the arrangement of these can differ markedly in different species. Figure 2 illustrates the arrangement of the λ light chain genetic loci (translocons) in humans, the chicken and the shark (sandbar and horned). Figure 2 also depicts the arrangement of the heavy chain translocons in humans and in the horned shark. It is the definitive characteristic of immunoglobulins (and antigen-specific T cell receptors) that at least two gene rearrangements are required to form functional genes with clonal restriction of the antigen-specific B cells (and T cells), but the fundamental or prototypic

Figure 2 Physical maps of (A) λ light chain and (B) μ heavy chain loci of human, chicken and shark. Curly brackets { } indicate unknown distances between gene segments on the same chromosome. Dotted lines indicate that it is not even known if the gene segments are on the same chromosome. The organization and distances of gene segments within parentheses () is unknown. ψ indicates a pseudogene. The maps are adapted from Lai *et al* (1989), McCormack and Thompson (1990), Shambloott and Litman (1989) and Hohman, Schluter and Marchalonis (1995).

The basic gene arrangement as illustrated by the human λ and μ chains is the type of configuration adopted by mammals, amphibians (frogs) and teleosts (fish). For each gene cluster, a large number of V regions is associated with a limited number of C regions. The whole V region repertoire is available for each C region. There are also numerous J and D (for μ chain) segments. Diversity is generated by randomly combining together through DNA rearrangement events single V(D)J elements with a C region to form a functional gene. In the chicken, there is only a single set of functional genes and all antibodies are derived from the same rearrangement event. Diversity is generated by gene conversion events between the single functionally rearranged V region and numerous V region pseudogenes. The arrangement in the shark is again quite different. Whereas in the situations described above diversity is generated by having many V regions or pseudo-V genes associated with a few C regions, in the shark

Unexpected multiplicity of immunoglobulins in lower vertebrates

Table 1 Comparison of amino acid sequences of heavy chain variable and μ chain constant regions of human, chicken, clawed toad and shark. Identities are shown boxed or circled. The alignments were carried out according to the procedure of Feng and Doolittle, with sequence data referenced in Marchalonis and Schluter (FASEB Journal, 1989). V_H and C_H domains are placed with reference to the human sequence according to Kabat. Sources of sequences: a) human - myeloma protein gel from the Genbank database; b) chicken - V region is cDNA clone 3W-25 from Reynaud *et al* (1989). C region is from the Genbank database; c) clawed toad (*Xenopus*) - from Schwager *et al* (1989); d) horned shark - V region is genomic clone 2809, DJC region is cDNA clone 12622 from Kokubu *et al* (1988). Citations are given in Marchalonis and Schluter (1989). Stars denote complete conservation among the four species

Table 2 Distribution of immunoglobulin classes among vertebrate classes

<i>Vertebrate class</i>	<i>Immunoglobulins</i>	<i>Light chain types documented</i>
Mammals	IgM, IgG, IgA, IgD, IgE	κ , λ
Birds	IgM, IgA, IgY, IgN	λ
Reptiles	IgM, IgY, IgN	Light chains present but uncharacterized
Amphibians	IgM, IgY, IgX	Three light chain types present
Lungfish	IgM, IgN	Light chains present but uncharacterized
Bony fish	IgM	Light chains of teleost type
Sharks/rays	IgM, IgW/NARC	λ , κ , other
Lampreys/hagfish	IgM(?)	Light chains present but uncharacterized
Protochordates	No 'classical immunoglobulin' but proteins cross-reactive with antibodies of shark and lampreys occur	

heavy chain containing one variable and six constant domains and may represent the primitive immunoglobulin in evolution. IgW variable domains resemble those of heavy chains, but are significantly different and show substantial variation in sequence consistent with the diversity to recognize a large number of antigens. Furthermore, major diversity both in isotypes and variable domain sequences has been found among light chains of cartilaginous fishes. The dominant family in carcharhine sharks (e.g. the sandbar shark) is a family related to the λ light chains of higher vertebrates, and this group itself consists of at least three major families containing more than two hundred separate genes. The dominant class of light chains in the nurse shark resembles mammalian κ chain and that in the horned shark is a separate type which appears to be restricted to the sharks.

Origin of variable region diversity

Investigations of mammals, birds and the *Xenopus* have indicated that two genes are required early in the development of T and B cells in order for recombination of variable, diversity and joining segments of immunoglobulin light and heavy chains and T cell receptor chains to occur. These have been termed RAG-1 (recombination activating gene 1) and RAG-2 (recombination activating gene 2). Although their mechanism of action is currently unknown, their presence is required in early T and B cells to allow recombination. Genes unequivocally homologous to the human RAG-1 gene occur in all jawed vertebrates including sharks, paddlefish, goldfish, *xenopus* and the axolotl. Comparison of the sequence of the complete 1113 amino acid shark RAG product with the human gene product shows regions of greater than 85% identity as well as segments of approximately 20–50% identity. All RAG-1 genes have homology to DNA-processing enzymes, expressing among other features the so-called RING

finger Zn-finger motif expressed by the yeast excision repair enzyme RAD18. Analysis of the shark sequence indicates that RAG-1 genes are members of the integrase family of site-specific DNA-rearrangement enzymes that have been studied in bacteria. Comparable analyses of sequence homology suggests that the vertebrate RAG-2 molecule is homologous to integration host factors that in bacteria act in concert with the integrases.

Origins of immunoglobulins

The evidence is now conclusive that the most primitive living vertebrates, the cyclostomes hagfish and lampreys, make antibodies comparable to those of higher vertebrates in charge dispersity and in consisting of two types of polypeptide chains (light and heavy) that can associate covalently by disulfide bonds. These molecules are serologically cross-reactive with those of elasmobranchs, but their protein and gene structure remain elusive at this time. The question of the origin of the rearranging immunoglobulin system likewise is a challenging contemporary problem. It is likely that this system arose in the deuterostome ancestors of vertebrates. Consistent with this hypothesis, molecules found in some protochordate species (tunicates) are antigenically related to heavy chains of sharks and lampreys and have sufficient mass (25–30 kDa) to contain the product of V and C gene segments. Whether these molecules prove to be the protoimmunoglobulin 'missing links' remains to be determined, but the search for the first vertebrate-type antibody continues to be a major issue in immunology.

IMMUNOGLOBULIN, FUNCTIONS

Dennis R Burton, Departments of Immunology and Molecular Biology, The Scripps Research Institute, California, USA

The function of immunoglobulin is in essence to link foreign material (antigen) to its means of elimination (effector system). Antigens come in all shapes and sizes, whereas the number of effector systems is small. This is reflected in the organization of the antibody molecule into variable (antigen recognition) and constant (effector recognition) parts. It is also reflected in the unusual degree of molecular flexibility found in antibodies and illustrated in Figure 1 for the major antibody in serum, IgG. Fab arm flexibility about the hinge (Y to T shape changes, Fab arm wagging) allows 'variable reach' for the antibody and therefore bivalent recognition of differently spaced antigens on, for example, a cell surface. The other Fab motions similarly should reduce the steric requirements in antigen conformation for antibody binding. Motions of Fab and Fc relative to one another should, in principle, assist in the simultaneous

binding of antigen and effector molecule and may in some cases be crucial.

The principal effector functions triggered by antibody are complement activation and cellular elimination mechanisms such as phagocytosis and antibody-dependent cellular cytotoxicity (ADCC). These functions are generally triggered only by antibody molecules clustered together as on a foreign cell surface and not by free unliganded antibody. This is crucial considering the high serum concentration of some antibodies. Effector molecule binding appears concentrated in the C_H2 domain of IgG or its equivalent in other antibody molecules.

Complement activation

The classical pathway of complement is triggered by the interaction of the first complement component, C1, either with IgG in an associated state (e.g.

Figure 1 Flexibility of the IgG molecule.

coating a target cell or aggregated by antigen in an immune complex) or with IgM bound to antigen.

C1 is a complex consisting of the subcomponents: C1q, C1r and C1s. It is C1q which interacts with antibody to initiate the enzymatic process of the pathway. This hexameric molecule, having the appearance of a 'bunch of tulips', is multivalent in its binding to antibody (**Figure 2**). This multivalency, rather than any conformational change, is probably the key to why complement is only triggered by IgG in an associated form. Binding of C1q to monomeric IgG is only weak ($K_a \sim 10^4 \text{ M}^{-1}$), whereas binding to associated IgG and the consequent use of two or more 'tulip heads' makes binding much tighter (K_a

Figure 2 Schematic representation of complement C1q interacting with two IgG molecules bound to antigen on a cell surface.

$\sim 10^8 \text{ M}^{-1}$), and allows the activation process to proceed. On the other hand, IgM is polymeric even in the absence of antigen and since one complexed IgM molecule will activate complement, it appears that binding to antigen does induce a conformational change in the antibody. It is suggested from electron microscope studies that this may involve movement of Fab arms relative to Fc in a 'star' to 'staple' transition. This process has been termed antibody dislocation and may also be important for the function of IgG.

The binding site for C1q on IgG includes a simple motif, Glu-X-Lys-X-Lys (318–322) located on the final β strand of the C_H2 domain and at least one residue from a nearby loop (Pro331). The charged residues in the linear sequence are directed out into the solvent, constituting a contiguous site, and the alternate residues (X) into the interior of the domain. The charged motif is one that is found in many proteins and its recognition in bacterial or viral arrays may have constituted an ancient defense mechanism. Later in evolution, the antibody may have appeared as an adaptor avoiding the requirement for the motif to be written directly on the pathogen.

Complement activation is strongly isotype-dependent. In any comparison it is important to distinguish C1q binding, C1 binding, C1 activation, and whole complement activation. The most widely used assay is the measurement of the end-product of the whole complement cascade, i.e. cell lysis. The inability of an IgG to promote efficient lysis does not necessarily indicate an inability to bind C1q; a later stage may be implicated. For example, C1q binding is not always related to C1 activation and later components of complement (e.g. C4b, C3b) also interact with IgG. Further, the source of complement can be an important factor in describing the ability of an isotype to activate the cascade. The human IgG subclasses as monomer bind C1q with measurable affinity in the order IgG3 > IgG1 > IgG2. IgG3 and IgG1 activate C1 and whole complement efficiently. IgG2 generally does not activate human complement. IgG4 does not bind C1 and does not activate complement. In other species, mouse IgG3, IgG2a and IgG2b, guinea pig IgG2, rabbit IgG, rat IgG2b, IgG1 and IgG2a bind C1q and activate complement. Mouse IgG1, guinea pig IgG1 and rat IgG2c bind C1q weakly, if at all, and do not significantly activate complement.

The alternative pathway of complement is activated weakly by associated IgA as immune complexes or coated on to microtiter plates. For human IgA, both subclasses and secretory IgA activate. An F(ab')₂ fragment is functional but isolated Fc or Fab fragments are not.

Fc receptor binding

A major effector system is the recognition of antibody-coated targets by cells bearing Fc receptors. These are found on a number of cell types and are associated with a number of functions including phagocytosis (monocytes, macrophages and granulocytes), ADCC (monocytes, macrophages, neutrophils and lymphocytes), anaphylaxis (mast cells) and maternofetal transport (trophoblasts). Receptors for all the classes of immunoglobulin have been described and those for IgG, IgE and IgA cloned.

Human leukocyte IgG Fc receptors can be grouped into three classes: FcγRI, FcγRII and FcγRIII. FcγRI (CD64) is found on monocytes, macrophages, dendritic cells and stimulated neutrophils and is often described simply as the 'high-affinity Fcγ receptor' because it binds monomeric human IgG1 and IgG3 with high affinity ($K_a \sim 10^8 \text{ M}^{-1}$). IgG4 is bound 10-fold more weakly and IgG2 not at all. Three very similar FcγRI genes have been identified although only one codes for the receptor which binds IgG. FcγRI can trigger a number of functions including internalization of small immune complexes, phagocytosis of antibody-coated erythrocytes, ADCC, enhancement of antigen presentation, cytokine release from monocytes and superoxide production in neutrophils.

FcγRII (CD32) is the most widely distributed class of FcγR and is found on most types of leukocytes. It is often described as a low-affinity receptor as it interacts only very weakly with monomer IgG ($K_a < 10^6 \text{ M}^{-1}$) although its interaction with certain IgG isotypes in associated form is much stronger. Three different FcγRII genes have been identified, giving rise to FcγRIIa, FcγRIIb and FcγRIIc receptors. FcγRIIa is found in two allotypic forms, termed high-responder (HR) and low-responder (LR) forms. The HR form binds well to associated human IgG1 and IgG3 but not with IgG2 or IgG4. The LR form also binds human IgG2. FcγRIIb binds well to associated IgG1 and IgG3, IgG4 with intermediate affinity and IgG2 very poorly. FcγRIIc probably resembles FcγRIIb in its IgG-binding profile. FcγRII can mediate many of the functions described for FcγRI. In addition, FcγRIIb is preferentially expressed on B cells where it appears to have a role in downregulation of B cell activation upon cross-linking with surface Ig. It is also expressed on mast cells where it downmodulates cell activation on cross-linking to FcεRI.

FcγRIII (CD16) is expressed as two gene products. FcγRIIIa is a transmembrane protein found on macrophages and natural killer (NK) cells and subsets of T cells and monocytes. It is the sole FcγR

found on NK cells. FcγRIIIa shows moderate affinity for human IgG1 and IgG3 (K_a approx. $3 \times 10^7 \text{ M}^{-1}$) and does not bind IgG2 or IgG4. FcγRIIIb is a glycosyl phosphatidylinositol (GPI)-anchored protein expressed exclusively on neutrophils. It shows low affinity for monomeric IgG ($K_a \ll 10^7 \text{ M}^{-1}$). FcγRIII molecules can mediate a variety of functions. Cross-linking of FcγRIIIa on activated NK cells can trigger apoptosis.

The binding site on IgG for FcγRI is believed to contain residues from the lower hinge ($C_{H1}2$ domain exon) centered around Leu235. This is the region attacked by pepsin in the commonly used procedure to generate $F(ab')_2$ fragments from IgG and probably explains its preservation. Involvement of this hinge region suggests a bent or dislocated conformation for IgG as it links antigen and Fc receptor (Figure 3). The lower hinge region has also been implicated in the binding of IgG to FcγRII and III, although it is believed that the details of recognition differ.

There are two human Fc receptors for IgE. FcεRI is found on mast cells and basophils where it binds monomer IgE with high affinity ($K_a \sim 10^{10} \text{ M}^{-1}$). It is also found on Langerhans cells and monocytes. Cross-linking of receptor-bound IgE by antigen (now often termed allergen) results in cell degranulation

Figure 3 Schematic representation of IgG molecule (lower hinge region site) linking an effector cell (upper membrane) via its Fc receptor (FcRI domain 2) to a target cell via two antigen molecules.

and the release of chemical mediators such as histamine which produce the symptoms of allergy. The binding site on IgE for FcεRI has been mapped to three loops of notable charged character in the C_H3 domain of IgE. Since the C_H3 domain in IgE is the structural equivalent of the C_H2 domain in IgG, it appears that this domain is once again crucial for effector activity. FcεRII (CD23) is found on inflammatory cells such as monocytes where it is probably related to IgE-mediated phagocytosis and on lymphocytes where it may have a role in modulating immune responses. It has low affinity for monomer IgE and the receptor-binding site has been associated with the C_H3 domain of IgE.

An Fc receptor for IgA (FcαR; CD89) has been described on a variety of cell types including neutrophils, eosinophils and monocytes. The receptor binds human serum and secretory IgA1 and IgA2 with relatively high affinity ($K_a \sim 5 \times 10^7 \text{ M}^{-1}$) and actively mediates ADCC, endocytosis, phagocytosis, triggering of cytokine release and antigen presentation.

Virus neutralization

Binding of antibodies to virus particles can render the particles noninfectious *in vitro* in a process termed neutralization. This is considered an important phenomenon since it frequently correlates with protection against virus challenge *in vivo*. The mechanism(s) of antibody neutralization are much discussed. It seems that inhibition of viral attachment to the target cell is one mechanism but that inhibition of fusion of the viral membrane of enveloped viruses with the target cell membrane is another. The possibility of the inhibition of events following virus entry has also been raised. In many cases, virus neutralization is effected by Fab fragments almost as well as whole antibody molecules, implying that aggregation of virions or cross-linking of envelope spikes is not important in those cases. Antibody may also have a role in complement-mediated lysis of viral particles. In some cases, it appears that subneutralizing concentrations of antibody can potentiate viral infection by increasing uptake of virus through interaction of the antibody-coated virus with Fc receptors (or through complement-antibody-virus particles with complement receptors) or via other nondefined mechanisms.

Catabolism

The level of IgG in blood is tightly regulated, with the rate of catabolism being determined by IgG concentration. Catabolism is accelerated under conditions of elevated IgG and reduced under conditions

of low IgG levels. This has been explained in terms of a 'protective receptor' which binds IgG, protects the molecule from degradation and then recycles it to the circulation. Saturation of the receptor will lead to accelerated catabolism if IgG levels rise. Recent studies have shown that this receptor in rodents is identical to the neonatal Fc receptor (FcRn) which has homology to the major histocompatibility complex (MHC) class I molecule. The interaction site on IgG is at the C_H2/C_H3 domain interface, overlapping the bacterial Fc receptor protein A site, and involving residues His310 and His433.

Other functions of antibody

All the immunoglobulin classes can be expressed at the surface of B cells where they act as antigen receptors, although this is primarily a function of IgM and IgD. Surface immunoglobulin possesses an extra C-terminal sequence compared to secreted immunoglobulin containing linker, transmembrane and cytoplasmic segments.

A number of immune responses including polyclonal antibody production, T cell-mediated responses such as antigen and alloantigen-induced proliferation, and cell-mediated cytotoxicity can be mediated by subfragments of Fc of IgG. A peptide corresponding to residues 335–358 of human IgG1, a sequence which spans the C_H2 and C_H3 domains, has been shown to induce polyclonal antibody production.

Classical immunology explains the precipitin reaction in terms of the formation of lattices through the bridging of antibody-combining sites by multivalent antigens. However, it is found that IgG and its F(ab')₂ fragment behave very differently in immune complex formation, implying a role for Fc–Fc interactions.

Rheumatoid factors are autoantibodies directed against epitopes expressed in the Fc region of IgG. Although most patients with rheumatoid arthritis show a heterogeneous population of rheumatoid factors, a common specificity has been detected in most rheumatoid sera. This antibody is of the IgM class and reacts with the C_H2–C_H3 interface region, showing many features in common with protein A.

Six distinct bacterial IgG Fc receptors have been designated types I–VI and a number of bacterial Fc receptors binding other isotypes of Ig have been described. The interaction of IgG and type I receptor, commonly termed protein A, has been studied in detail by crystallography and the site of binding between the C_H2 and C_H3 domains described.

The binding sites on antibodies for certain antigens occur with a single type of V_H segment with little

conservation of other elements in the V regions. These antigens, such as protein A (which has an Fc-binding site and a V_H-binding site on human V_H3 family antibodies), have been termed unconventional antigens or B cell superantigens.

IMMUNOGLOBULIN GENE SUPERFAMILY

Peter J Delves, Department of Immunology, University College London Medical School, London, UK

Many genes and their protein products share features that suggest a common ancestral origin and allow them to be grouped together into 'superfamilies'. The immunoglobulin (Ig) gene superfamily (or 'immunoglobulin superfamily', IgSF, when referring to the protein products of these genes) takes its name from the first members of this family to be sequenced and is one of the numerically largest of the various protein superfamilies. Proteins bearing IgSF domains exhibit a wide range of activities (Table 1), many of them having functions unrelated to the immune system, for example in the nervous system. This diversity of function is a reflection of the versatility of the Ig domain, a structure of about 70–110 amino acids which comprises a series of nonparallel β strands that are folded into two β sheets. This folding pattern (the 'Ig fold' Figure 1) is stabilized by a hydrophobic interior, and usually, but not always, by the possession of a characteristic disulfide bond between the sheets. The domain provides a stable platform for the display of specific determinants on

the outer faces of the β sheets or on the loops joining the β strands.

The criterion for inclusion in the IgSF is the presence of one or more Ig-type domains (Ig homology units) which confer upon the polypeptide a globular tertiary structure. Many proteins will contain IgSF domains together with other types of domains. For example the extracellular portion of the CD130 molecule is composed of one IgSF domain, one cytokine receptor domain, and four fibronectin type III domains. Such proteins are best referred to as mosaic proteins rather than as belonging to a particular superfamily. Although confirmation of the presence of an IgSF domain in any given protein is dependent upon X-ray crystallographic analysis, nucleic acid sequence comparisons with IgSF members whose crystal structure is known (e.g. Ig V and C domains, MHC class I α_3 domain), and with other members can provide strong support for inclusion in the superfamily. Further evidence can be obtained using circular dichroism to ascertain β sheet and α helical

Table 1 Some examples of proteins which contain IgSF domains

Protein	Mol. wt ^a (kDa)	Ig domains			Human chromosome	Function
		C1	C2	V		
CD1	43–49	1	–	–	1q22–q23	Presentation of peptide and lipid antigens to T cells
CD2	45–58	–	1	1	1p13.1	Signal transduction Ligand for CD48 and CD58
CD3 γ chain	25–28	–	1	–	11q23	TCR signal transduction
CD3 δ chain	20	–	1	–	11q23	TCR signal transduction
CD3 ϵ chain	19–20	–	1	–	11q23	TCR signal transduction
CD4	55–59	–	2	2	12pter–p12	TCR coreceptor Ligand for nonpolymorphic region of MHC class II
CD7	40	–	–	1	17p25.2–q25.3	T cell activation
CD8 α chain	32–38	–	–	1	2p12	TCR coreceptor Ligand for nonpolymorphic region of MHC class I
CD8 β chain	30–34	–	–	1	2p12	Homodimer or heterodimer with CD8 β chain TCR coreceptor Forms heterodimer with CD8 α
CD16 (Fc γ RIII)	48–70	–	2	–	1q23	Low/medium-affinity Fc receptor for IgG
CD19	95	–	2	–	16p11.2	Part of signaling complex for B cells
CD22	130–150	–	6	1	19q13.1	Negative signaling in B cells
CD28	44	–	–	1	2q33–q34	T cell activation Homodimer Ligand for CD80 and CD86
CD31 (PECAM-1)	140	–	6	–	17q23–ter	Adhesion
CD32 (Fc γ RII)	40	–	2	–	1q23–24	Low affinity Fc receptor for IgG
CD33	67	–	1	1	19q13.3	Adhesion
CD47	47–52	–	–	1	3q13.1–q13.2	Adhesion
CD48 (Blast-1)	41	–	1	1	1q21–q23	Ligand for CD2
CD50 (ICAM-3)	130	–	5	–	19p13.3–13.2	Ligand for LFA-1 (CD11a/CD18)
CD54 (ICAM-1)	90	–	5	–	19p13.3–13.2	Ligand for integrins including LFA-1
CD56 (NCAM)	175–185	–	5	–	11q23.1	Homotypic adhesion
CD58 (LFA-3)	40–65	–	1	1	1p13.1	Ligand for CD2
CD64 (Fc γ RI)	72–75	–	3	–	1q21.1	High-affinity Fc receptor for IgG
CD66a (CEA)	160–180	–	3	1	19q13.1–2	Adhesion
CD66b (CEA)	95–100	–	2	1	19q13.1–2	Adhesion
CD66c (CEA)	90–95	–	2	1	19q13.1–2	Adhesion
CD66d (CEA)	30	–	–	1	19q13.1–2	Adhesion
CD79a	47	–	1	–	19q13.2	BCR signal transduction
CD79b	37	–	–	1	17q23	BCR signal transduction
CD80 (B7-1)	60	–	1	1	3q21	T cell activation Ligand for CD28 and CD152
CD83	45	–	–	1	6p23–p21.3	Dendritic cell function
CD86 (B7-2)	75	–	1	1	3q13–q23	T cell activation Ligand for CD28 and CD152
CD89 (Fc α R)	55–100	–	2	–	19q13.4	Fc receptor for IgA
CD90 (Thy-1)	17–35	–	–	1	11q23.3	T cell activation
CD96 (Tactile)	160	–	–	3	Not known	Not known
CD100	150	–	1	–	Not known	Lymphocyte activation Homodimer
CD101	140	–	–	7	1p13	T cell activation Homodimer
CD102 (ICAM-2)	55–65	–	2	–	17q23–q25	Ligand for integrins

Table 1 Continued

Protein	Mol. wt ^a (kDa)	Ig domains			Human chromosome	Function
		C1	C2	V		
CD106 (VCAM-1)	95–100	–	7	–	1p31–p32	Ligand for integrins
CD114 (G-CSFR)	130	–	1	–	1p35–p34.3	G-CSF receptor

TCR δ chain	40–60	1	–	1	14q11.2	T cell antigen receptor for peptide–MHC
MHC class I α chain	44	1	–	–	6p21.3	Presents peptides to TCR on CD8 ⁺ T cells
MHC class II α chain	33–35	1	–	–	6p21.3	Presents peptides to TCR on CD4 ⁺ T cells
MHC class II β chain	28–30	1	–	–	6p21.3	Presents peptides to TCR on CD4 ⁺ T cells
Fc ϵ RI α chain	45–65	–	2	–	1q23	High-affinity Fc receptor for IgE
IL-1R accessory protein	70–90	–	2	1	Not known	IL-1 receptor accessory protein
IL-11R α chain	150	–	1	–	9p13	Low-affinity IL-11 receptor Heterodimer with CD130 forms high-affinity IL-11 receptor
Ly-9	90–120	–	2	2	1q22	Not known
MAdCAM-1	58–66	–	2	–	10	Lymphocyte homing Ligand for integrins
Sialoadhesin	185	–	16	1	20p13	Adhesion

^aRefers to apparent molecular weight on reduced SDS-PAGE. Note that primary function is not necessarily mediated by IgSF domain (for example, MHC–peptide-binding groove is formed by the non-IgSF domains of the MHC molecules).

content. The minority of Ig-type domains which lack disulfide bonds (e.g. the first domain of CD2 and the third domain of CD4) usually have hydrophobic amino acids which point inward and contribute to the hydrophobic interior between the β sheets. The

exon–intron gene structure can also be indicative of IgSF membership in that each Ig-type domain is usually encoded by one exon. Exceptions to this arrangement include the first domain of CD4. IgSF members are generally spread throughout the

Figure 1 Schematic drawing of an immunoglobulin variable domain showing the characteristic 'immunoglobulin fold'. (Copyright by Jane S. Richardson, reproduced with permission.)

chromosomes, although some members are genetically linked together. For example CD90(Thy-1), CD-56(NCAM) and CD3 ϵ , γ and δ are all found on chromosome 11 at band position q23.

One commonly used approach for sequence comparisons with known members of the superfamily utilizes the Dayhoff ALIGN program which scores similarities between the candidate sequence and several sequences from accepted Ig gene superfamily members. The alignments used for such sequence comparisons need careful consideration, taking into account such factors as the β strand/loop organization and the repertoire of conserved amino acids. No residue is invariant in all Ig-related domains and the primary structure of the Ig-type domains can be very different. This is vividly illustrated by the Ig variable region genes where even proteins encoded by the same gene family are sometimes <20% similar. Three domain patterns have been identified in the Ig gene superfamily, namely the V-, C1- and C2-related domains. Each domain consists of two β sheets forming the characteristic sandwich structure of the Ig fold. The V domain structure has an additional loop which, in Ig, forms the second hypervariable region. The C2 type domain is more compact than the C1 and V domains and although it shares with

C1 the lack of the additional loop found in V domains it appears, overall, to have a relatively equidistant relationship to both V and C1 domain types. Some IgSF members possess Ig-type domains which exhibit features that make them somewhat difficult to assign to any one of the previously defined groups.

Since the members of the Ig superfamily are mostly located in environments in which proteases are common, it has been suggested that selection for resistance to proteolysis may be the key factor in conservation of sequence pattern yielding a compact globular structure. Indeed, the transmembrane and cytoplasmic regions of the Ig gene superfamily members are extremely diverse. For example, Thy-1 lacks a cytoplasmic domain and utilizes a glycosphospholipid membrane anchor, whereas the CSF-1 receptor (CD115) has a long cytoplasmic domain which exhibits tyrosine kinase activity.

Although molecules of the Ig superfamily have diverse biological roles, a common theme among them is that homophilic (e.g. CD56-CD56) or heterophilic (e.g. CD2-CD58) interactions between domains on different polypeptide chains are involved in their function. This has led to the suggestion that the superfamily has evolved from a single cell surface domain that was capable of homophilic interaction between cells. The existence of Ig superfamily members (fasciclin, neuroglian and amalgam) in insects and perhaps even in bacteria suggests that diversification of the domain occurred early in evolution. Gene duplication and subsequent divergence would allow the development of multidomain structures with diverse functions. Extensive diversification in the superfamily probably allowed heterophilic recognition between related molecules, leading to the sophisticated interactions seen in vertebrate immune systems.

IMMUNOGLOBULIN GENES

Ian M Tomlinson, Medical Research Council Centre for Protein Engineering, Cambridge, UK

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The structural diversity required for antigen recognition is encoded by a complex array of immunoglobulin genes. This entry will deal primarily with human immunoglobulin genes as they are the only ones to date that have been completely mapped and sequenced. These genes span approximately four million base pairs of DNA, over 0.1% of the estimated three thousand million base pairs in the human genome.

The heavy and light chains of the immunoglobulin molecule are derived from separate sets of immunoglobulin genes located on different chromosomes. Although the heavy chain (H) genes are located in a single locus on human chromosome 14 (mouse chromosome 12), the light chain genes can be derived from one of two loci: kappa (κ) on human chromosome 2 (mouse chromosome 6) or lambda (λ) on human chromosome 22 (mouse chromosome 16). The organization of the genes in each of these clusters mimics the domain structure of the heavy and light chain polypeptides. Thus, the heavy chain, κ light chain and λ light chain loci have variable region genes that encode the variable domain (responsible for antigen binding) and constant region genes that encode the constant domain (responsible for various effector functions, see below).

Constant region genes

In humans, there are nine functional heavy chain constant region genes (C_{μ} , C_{δ} , $C_{\gamma 3}$, $C_{\gamma 1}$, $C_{\alpha 1}$, $C_{\gamma 2}$, $C_{\gamma 4}$, C_{ϵ} and $C_{\alpha 2}$; **Figure 1A**), one κ light chain constant region gene (C_{κ} ; **Figure 1B**) and four functional λ light chain constant region genes ($C_{\lambda 1}$, $C_{\lambda 2}$, $C_{\lambda 3}$

and $C_{\lambda 7}$; **Figure 1C**) (see **Table 1**). The constant region genes expressed by a particular B cell determine the immunoglobulin's isotype. Initially each B cell expresses the C_{μ} gene in association with one of the five light chain constant region genes (producing the immunoglobulin M (IgM) isotype). Note that κ and λ light chains are rarely or never expressed in the same B cell. The mechanism that enables immunoglobulins other than the IgM isotype to be expressed is known as 'class switching'. This involves a recombination event at the DNA level between 'switch' sequences upstream of the C_{μ} gene and those upstream of the C_{γ} , C_{ϵ} and C_{α} genes, resulting in the expression of the IgG, IgE and IgA isotypes, respectively (this deletes the intervening region of DNA). In the case of the IgD isotype, the C_{δ} gene is sufficiently close to the C_{μ} gene to be spliced into the J_{H1} segment at the RNA level (see **Figure 1A**). Thus, IgD is an exception in that it can be coexpressed along with IgM by the same B cell.

Table 1 Number of functional variable and constant region genes

	Human			Mouse		
	κ	λ	H	κ	λ	H
Variable (V) segments	40	30	51	?	3	?
Diversity (D) segment	—	—	25	—	—	13
Joining (J) segments	5	4	6	4	3	4
Constant genes	1	4	9	1	3	8

Figure 1 Organization of the human immunoglobulin genes. (A) The human immunoglobulin heavy chain genes (IGH) are located on chromosome 14q32.3. A schematic of the organization of the locus is shown (not to scale). Clusters of V_H, D and J_H segments are located upstream of the constant region genes (values in parentheses indicate the number of functional elements in each cluster). The entire locus including the constant region genes is approximately 1400 kb long. (B) The human immunoglobulin κ light chain genes (IGK) are located on chromosome 2p11-12. A schematic of the organization of the locus is shown (not to scale). Clusters of V_K and J_K segments are located upstream of the single constant region gene (values in parentheses indicate the number of functional elements in each cluster). The entire locus is approximately 1700 kb long. (C) The human immunoglobulin λ light chain genes (IGL) are located on chromosome 22q11.2. A schematic of the organization of the locus is shown (not to scale). Clusters of V_L segments are located upstream of the four functional J_L-C_L pairs (values in parentheses indicate the number of functional elements in each cluster). The entire locus including the constant region genes is approximately 900 kb long.

Somatic recombination of variable region genes

In contrast to the constant region genes, almost every B cell expresses a different pair of heavy and light chain variable region genes. This diversity is generated during B cell development by somatic recombination at the DNA level of a relatively small number of basic building blocks: V_H (variable), D (diversity) and J_H (joining) segments for the heavy chain variable region gene and V_K and J_K segments (kappa) or V_L and J_L segments (lambda) for the light chain variable region gene (the light chain does not use D segments). Each of these germline segments has a recombination signal sequence (adjacent to the 3' end of the V segment, both ends of the D segment and the 5' end of the J segment) that consists of a

conserved heptamer, a less-conserved nonamer and a 12 or 23 base pair spacer. The heptamer and nonamer sequences at the 3' ends of the V and D segments are complementary to those at the 5' end of the D and J segments, respectively. When recombination of the germline segments takes place, the complementary regions come together and the two segments fuse to form a rearranged variable region gene (see Figure 2 for details). Although the precise mechanism of recombination is unknown it must specifically recognize the recombination signal sequence, since a 12 base pair spacer will only pair with a 23 base pair spacer (the '12/23 rule'). The immune system uses this to great effect, in that V_H and J_H segments (that have 23 base pair spacers) cannot recombine with themselves or with each other, only with D segments (that have 12 base pair

Figure 2 VDJ recombination. A vast repertoire of different heavy chains is created by the combinatorial rearrangement of a small number of variable (V_H), diversity (D) and joining (J_H) segments. In this example the hypothetical V_H segment 'V_{H2}' rearranges to the D segment 'D₂' and the J_H segment 'J_{H2}'. At the DNA level the heavy chain locus (A) first undergoes a D-J_H join, the intervening region of DNA being deleted to produce (B). This is followed by V_H-D joining to produce a rearranged V_H gene (C). The remaining J_H segments are removed after transcription (D) by RNA splicing that deletes the leader intron in the V_H segment, the J-C intron and the introns within the constant region gene (here the membrane form of IgM is produced that consists of six exons). Translation of the resulting mRNA (E) produces a functional heavy chain polypeptide (F). A similar rearrangement process occurs for the light chain polypeptide, except that there are no D segments (just a single V_κ-J_κ or V_λ-J_λ join) and the constant region is encoded by a single exon.

spacers). When recombination occurs between two segments in the same transcriptional orientation (both 5' to 3' with respect to the constant region gene/s) the intervening DNA is deleted from the genome and is lost in subsequent cell division (deletional joining). Occasionally (for example in the κ locus, see below) the two segments that recombine are in opposite orientations. In this case, the segments fuse as normal but the intervening DNA is inverted and maintained in the genome (invert joining).

In addition to enabling different V, D and J segments to come together (so-called combinatorial or germline diversity), the mechanism of recombination itself creates significant diversity due to imprecise joining and the incorporation of untemplated nucleotides at the join (junctional diversity). One consequence of this junctional diversity is that the D segment can be encoded in all three reading frames. Given that different heavy chains can also pair with different light chains the potential diversity created purely by somatic recombination is huge, although the actual diversity at any given time is limited by the number of B cells in the body (between 10^{11} and

10^{12} in humans). Antibodies selected from this 'primary repertoire' are believed to be able to bind antigen with at least moderate affinity.

Somatic hypermutation of variable region genes

The affinity of the antibody-antigen interaction is subsequently improved by somatic hypermutation of the rearranged genes followed by further rounds of selection (a process known as affinity maturation). These mutations are confined to the variable region gene and are primarily nucleotide substitutions, rather than insertions or deletions. The accumulation of multiple mutations occurs in a stepwise manner by the introduction of single nucleotide substitutions, followed by selection for and proliferation of B cells with higher affinity variants. Although the heavy and light chain variable region genes may only pick up a handful of mutations during this iterative process, mice immunized with various hapten antigens have been shown to express mutated antibodies with

affinities 10–100-fold higher than that of the unmutated clone.

Thus the structural diversity that forms the basis of antigen recognition is underpinned by a genetic diversity created in three ways: by the combinatorial rearrangement of different V, D and J segments (germline diversity), by junctional diversity produced during the recombination of these segments and later by somatic hypermutation that introduces point mutations into the rearranged heavy and light chain variable region genes. A prerequisite to dissecting the relative contributions of these three types of diversity is a complete description of the sequences and chromosomal organization of the germline V, D and J segments. Although the constant region genes were mapped and sequenced at the beginning of the 1980s, the mapping and sequencing of the human V, D and J segments have only recently been completed. The delay was mainly due to the number of segments and their homology to one another. This also confused early estimates of the total number of segments that suggested there may be as many as a thousand different V_H and V_κ segments.

Human germline V_H , D and J_H segments

The human V_H , D and J_H segments span 1100 kilobases (kb) of DNA upstream of the nine functional constant region genes (that span 300 kb) on chromosome 14q32.3 (Figure 1A). The transcriptional orientation of all segments in the locus (5' to 3' with respect to the constant region genes) is consistent with V_H –D and D– J_H joining occurring by a deletional mechanism (see above). There are a total of 51 functional V_H segments (Table 1), far fewer than originally anticipated, that can be divided into six main families (V_H1 to V_H6) on the basis of nucleotide homology of 80% or above. An additional family, V_H7 , is closely related but distinct from the V_H1 family. Functional members of the seven different V_H families are interspersed throughout the locus (along with at least 40 nonfunctional pseudogenes), in contrast to the organization of the mouse V_H locus, where family members are clustered. Interestingly, the genomic clone used to map the J_H -distal end of the locus was isolated by its ability to provide functional human telomere activity in yeast, indicating that the V_H locus is located within a few kilobases of the end of the long arm of the chromosome 14. Human D segments are also divided into six main families. These are arranged in four clusters (24 functional D segments) located between the single V_H6 family member and the J_H segments. An additional D segment, D_{11Q52} (homologous to the mouse D segment D_{Q52}), is located immediately upstream of the

six functional J_H segments, making a total of 25 functional D segments (Table 1). In addition to the functional V_H and D segments on chromosome 14, many V_H segments and more than one cluster of D segments are located on chromosomes 15 and 16. These so-called 'orphan' segments are not associated with J_H segments or constant region genes and therefore cannot encode functional heavy chains.

Human germline V_κ and J_κ segments

In humans, approximately 60% of light chains are of the κ type. A total of 40 functional V_κ and five J_κ segments are located on chromosome 2p11–12 upstream of the single C_κ gene (Table 1 and Figure 1B). The functional V_κ segments are divided into six families ($V_\kappa I$ to $V_\kappa VI$) based on nucleotide homology. These are arranged to two separate clusters: with 22 functional V_κ segments in the J_κ -proximal region spanning 450 kb (20 of these segments rearrange by deletional joining to the J_κ segments whereas two rearrange by invert joining) and 18 in the J_κ -distal region spanning 400 kb (all of these segments rearrange by invert joining). An additional 36 pseudogenes are interspersed amongst the functional segments. These two regions are separated by 800 kb of DNA that does not contain any V_κ segments. A comparison of the organization and V_κ segment content of the J_κ -proximal and J_κ -distal regions indicates that they are the result of a recent duplication event: on average, the sequences of the V_κ segments in the J_κ -proximal region differ by less than 1% from the corresponding segments in the J_κ -distal region. Studies of expressed κ chains have shown that V_κ segments in the J_κ -distal region are rarely used compared to those in the J_κ -proximal region. This is probably due to their distance from the J_κ segments and/or the fact that they must rearrange by inversion (see above). At least 24 additional V_κ segments are located outside the functional locus, some downstream of the functional locus on chromosome 2, some on the long arm of chromosome 2 and others on chromosomes 1 and 22. None of these 'orphan' segments are functional.

Human germline V_λ and J_λ segments

In humans, approximately 40% of light chains are of the λ type. The human immunoglobulin λ locus is located on chromosome 22q11.2 and contains 30 functional V_λ segments (Table 1) from ten V_λ families ($V_\lambda1$ to $V_\lambda10$) (Figure 1C). The transcriptional orientation of all segments in the locus (5' to 3' with respect to the constant region genes) is consistent with V_λ – J_λ joining occurring by a deletional mech-

anism. As with the human V_H and V_K segments, many pseudogenes are scattered throughout the locus. The J_λ segments in the λ locus are each paired with their own C_λ gene, such that there are four functional J_λ - C_λ pairs (Table 1 and Figure 1C). The choice of C_λ gene expression is therefore determined by V_λ - J_λ rearrangement. In contrast to the human heavy chain and κ light chain loci, where members of different V_H and V_K families are interspersed throughout the locus, the V_λ families are arranged in three distinct clusters. Cluster A (closest to the J_λ segments) contains the $V_{\lambda 2}$ and $V_{\lambda 3}$ families, cluster B (in the middle of the locus) contains the $V_{\lambda 1}$, $V_{\lambda 5}$, $V_{\lambda 7}$ and $V_{\lambda 9}$ families and cluster C (furthest from the J_λ segments) contains the $V_{\lambda 4}$, $V_{\lambda 6}$, $V_{\lambda 8}$ and $V_{\lambda 10}$ families. In addition to the functional genes on chromosome 22 at least one nonfunctional 'orphan' V_λ segment is located on chromosome 8.

For further details on the sequences and organization of the human V, D and J segments see <http://www.mrc-cpe.cam.ac.uk/imt-doc/vbase-home-page.html> on the World Wide Web.

The creation of antibody diversity

Early studies on rearranged genes by Kabat and colleagues demonstrated that sequence diversity in antibodies is concentrated in six complementarity-determining regions (CDRs), three from the heavy chain variable domain (CDRH1, CDRH2 and CDRH3) and three from the light chain variable domain (CDRL1, CDRL2 and CDRL3). In the primary repertoire the CDRH1 and CDRH2 regions are encoded by the V_H segment, whereas CDRH3 is the product of V_H -D- J_H recombination. For the light chain, CDRL1, CDRL2 and the beginning of CDRL3 are encoded by the V_K or V_λ segment, whereas the end of CDRL3 is the product of V_K - J_K or V_λ - J_λ recombination. Subsequent crystallographic analyses have shown that these six CDRs correspond to the six antigen-binding loops that together form the antigen binding site of the antibody. As we have seen, this diversity is the result of germline diversity and junctional diversity in the primary repertoire and somatic hypermutation introduced during the process of affinity maturation. Since all human V_H , V_K and V_λ segments have now been sequenced and mapped it is possible to dissect their respective contributions in response to a wide range of antigens. A large database of rearranged genes was compiled and each was automatically assigned to its germline V_H , V_K and V_λ counterpart, thereby identifying the location of the somatic mutations in each rearranged gene. The percentage somatic hypermutation at each position in the heavy and light chain variable

Figure 3 The patterns of germline diversity and somatic hypermutation. For each position, percentage somatic hypermutation (top of each panel, lighter tint) and germline variability (bottom of each panel, darker tint) are shown for (A) the human V_H domain and (B) the human V_K domain (corresponding plots for the V_λ domain are not shown here but can be found in Ignatovich *et al* (1997)). (Reproduced with permission from Tomlinson *et al* (1996).)

domains was then calculated (Figure 3). The CDRH3 and the end of the CDRL3 were not included in this analysis, as somatic hypermutation could not be distinguished from junctional diversity in this region. To compare the diversity introduced by somatic hypermutation with that present in the *same* repertoire of germline sequences, each of the rearranged genes was substituted with its corresponding germline V_H , V_K and V_λ segment. Germline diversity at each position was then calculated using the Kabat variability index (Figure 3).

Germline diversity is found mostly in CDRH2, at residue 50 in the CDRL2 and at residues 91, 92 and 94 in the CDRL3. In contrast, somatic hypermutation is most prevalent in the CDRH1 and CDRL1 regions. In order to illustrate these patterns of germline diversity and somatic hypermutation, a representative antibody structure was used to provide an 'antigen's eye' view of the binding site. Before

somatic hypermutation, germline diversity is concentrated at the centre of the antigen binding site. In contrast, somatic hypermutation spreads diversity to regions at the periphery of the binding site that are highly conserved in the primary repertoire. As a result, the final pattern of diversity (similar to that first represented by Kabat) is evenly distributed across the antigen binding site (see color plate 7).

The complementarity between germline diversity and somatic hypermutation seems to have evolved as an efficient strategy for producing high-affinity antibodies, given the limited number of B cells available for selection. Thus, antibodies are first selected from the primary repertoire based solely on the diversity at the center of the binding site. Somatic hypermutation is then left to optimize residues at the periphery without disrupting favorable interactions established during the primary response. The availability of a mechanism for somatic hypermutation has clearly led to the conservation of some sites in the germline V gene segments (for alteration by somatic hypermutation) and to the diversification of others. In this way, somatic hypermutation has left an evolutionary imprint on the repertoire of human germline V gene segments.

IMMUNOGLOBULIN STRUCTURE

Allen B Edmundson and Kim N Andersen, Oklahoma Medical Research Foundation, Oklahoma City, Oklahoma, USA
Copyright © 1998 Elsevier Ltd. All Rights Reserved.

An antibody molecule consists of four polypeptide chains or multiples thereof. There are two L ('light') chains and two H ('heavy') chains, with the H chains approximately twice as long as the L chains. Among human immunoglobulins there are two groups of L chains (κ and λ) and five classes of H chains (α , γ , δ , ϵ and μ), all with distinct amino acid sequences and antigenic properties. L Chains can associate with any of the H chain classes, producing immunoglobulin A (IgA) (with α -type H chains), IgG (γ), IgD (δ), IgE (ϵ), and IgM (μ) immunoglobulins.

Each type of antibody plays a different role in the body. IgA molecules are distributed both in the serum and in secretory fluids from the salivary glands and gastrointestinal tract. IgG proteins are the most abundant antibodies in serum, while IgD molecules are found predominantly on the surface of B lymphocytes. IgE antibodies are mediators of allergic responses and of immune reactions to parasitic infections. IgM proteins occur in two forms: 1) membrane-bound receptors on B cell surfaces and 2) secreted molecules assembled into pentamers or hexamers, with a molecular weight of approximately 900 kDa – hence the popular name of 'macroglobulin' for an IgM molecule in serum.

Components of an antibody and the genes that encode them

Both the L and H chains are composed of globular 'domains' connected by flexible segments with extended conformations, like cylindrical beads on a string (see **Figures 1–5**). An L chain has two domains – a V ('variable') unit with 108–111 amino acid residues, and a C ('constant') unit with about 105 residues (**Figure 1**). The variable domain is so named because its amino acid sequence differs from protein to protein, even within the same antigenic class and species. Within each isotype, the sequence of the constant domain changes very little (usually in four or fewer positions). Each V domain is encoded by two genes. The V_L gene specifies the first 95 residues and the J_L ('joining') gene dictates the remainder. Both the V_L and J_L gene products contribute to the antigen-binding site of the antibody (i.e. the CDRs, the 'complementarity-determining regions') and to the FRs ('framework regions') of the domain. The tail of the J_L segment joins the first few residues

of the C_L domain to form the flexible 'switch' region bridging the V and C domains.

In an H chain, the V domain is composed of the products of three genes: V_H , D ('diversity') and J_H . V_H encodes CDR1 and 2, as well as FR1, 2 and 3, and all three genes share responsibility for CDR3. J_H specifies FR4 and part of the switch region. Three C domains (four in IgM and IgE molecules), each encoded by a single gene (C_{H1} , C_{H2} , and C_{H3}), are connected to the V_H domain in human antibodies.

In IgG proteins the repeating unit is the combination of one L and one H chain (L–H heterodimer), normally linked covalently by an interchain disulfide bond. V_L and V_H domains are paired via noncovalent interactions to form an Fv ('fragment, variable') region, at the tip of which is the binding site for antigen. Pairing interactions of the C_L and C_{H1} domains involve a different set of surfaces than those of the V domains (see section on 'The immunoglobulin fold', below). Together, these V and C pairs constitute the Fab ('fragment, antigen-binding') (**Figure 2**).

To produce the normal four-chain IgG structure, the H chains in two L–H heterodimers are held together covalently by at least one interchain disulfide bond and noncovalently by very tight interactions between the C_{H3} domains. The combination of the C_{H2} and C_{H3} domains from the two heavy chains is called the Fc ('fragment, crystalline'), since this unit tends to crystallize when released from an IgG molecule by the enzyme papain (**Figure 3**).

The immunoglobulin fold

A single disulfide bond enclosing a loop of 65–70 residues is a common feature of every domain in L and H chains. The locations of the intrachain disulfide bonds in the V_L and C_L domains of a human λ -type light chain are shown in **Figure 1**. This illustrates the general repeated structural motif seen in antibodies: β sandwich or β barrel domains connected by flexible polypeptide segments. In an individual domain, the 'immunoglobulin fold' consists of two layers of antiparallel β pleated sheets linked by an intrachain disulfide bond. As exemplified by C domains, one sheet contains three strands of polypeptide chain and the second sheet has four strands. These sheets are not as clearly defined in all V domains. For instance, strand 1 of the four-chain layer may participate in few cross-strand hydrogen

Figure 1 Tracing of the light chain from a human (Mcg) Bence Jones dimer with directional arrows superimposed (drawing by Kathryn R. Ely). The 3-stranded β -pleated sheets are represented by striated arrows and the 4-stranded layers by white arrows. The intrachain disulfide bonds are represented by the black bars between the β -pleated sheets. Positions of strategically located residues are numbered and the NH_2 - and COOH -termini are labeled N and C. The ascending and descending arms of CDR2 (marked by residue 53) form two additional β -strands in some molecules and expand the top layer to a 5-chain β -pleated sheet. The two domains can be approximately superimposed if the V_L domain is rotated 165° and translated $44 \text{ \AA}$. The V and C domains can be defined as rotational allomers, molecules related by rotation with similar 3-dimensional structures but different amino acid sequences.

bonds. The extra loops comprising CDR2 at the tip of the domain (but not present in C domains) may or may not exhibit the hydrogen bonding patterns that would expand the three-chain layer to a five-stranded sheet. These differences give the V domains more of a cylindrical outline and make them appear more like a barrel than a sandwich.

In antibodies the three-stranded sheets (or five-strand expanded sheets) provide the interface of the V_L - V_H pair, while the four-stranded sheets are exposed to solvent. The antigen-binding sites are composed mainly of three CDRs from each chain and are located at the outer edges of the three- or five-stranded sheets. Conserved FR residues bordering the CDR loops may also provide contact residues for binding an antigen, particularly in large active sites.

The modes of domain pairing are significantly different in the C domains. Relative to the V domains, the C_L and $\text{C}_\text{H}1$ domains rotate 160° - 180° . Their four-stranded β pleated sheets cross to form very close contacts which stabilize the dimer. The four-stranded layers of both the C_L - $\text{C}_\text{H}1$ and $\text{C}_\text{H}3$ - $\text{C}_\text{H}3$

dimers face each other to produce tight packing interactions and the three-stranded sheets are now relegated to the outer surfaces of each pair. Opposing faces of the $\text{C}_\text{H}2$ domains also involve the four-stranded sheets. However, covalently linked oligosaccharides partially cover the surfaces and effectively prevent close contacts of the protein moieties. Strict two-fold symmetry between half molecules of human and rabbit IgG antibodies may be broken because one of the oligosaccharide chains is shorter than the other (e.g. in 10-15% of patients with rheumatoid arthritis and in most if not all normal rabbits).

The λ light chain in **Figure 1** is covalently linked to the heavy chain by an interchain disulfide bond involving the penultimate residue. In a κ light chain, the C-terminal residue would serve this function. The interchain half-cystine residue contributed by the heavy chain is located in the 'hinge' region of a human IgG antibody (see 'Hinge region' below). However, the half-cystine residue in an IgM heavy chain is found in the sequence encoded by the $\text{C}_\text{H}1$ gene. In both cases, the strands containing the half-

Figure 2 The model of the complex of the NC6.8 Fab with its haptent, N-(p-cyanophenyl)-N'-(diphenylmethyl)-N''-(carboxymethyl)guanidine. This haptent is shown as a ball-and-stick model between the V domains and the details of the constituent parts are enlarged above the arrow. When added to crystals of the native (unliganded) Fab, the haptent causes the crystals to dissolve. Immediately adjacent, new crystals of the haptent-Fab complex appear and these crystals have a different physical appearance, space group and unit cell dimensions. Relative to the native structure, the light chain of the complex is extended by 10 Å and the angle between V_L and C_L is increased by 20°. The heavy chain is shortened commensurately by flexing and the angle between V_H and C_H1 is decreased by 22°.

Figure 3 Model of an Fc from a human IgG1 myeloma protein. The carbohydrate (CHO) moiety is only shown for one C_H2 . The hinge region is asymmetrically placed above the C_H2 domains and the two polypeptide strands are linked by interchain disulfide bonds (black bars).

cystine-residues closely approach the C-terminal region of the light chain in the three-dimensional structures of the antibodies.

Structures of antigen-binding sites

The crystal structure of the NC6.8 Fab with its ligand bound in the active site is presented in **Figure 2**. Sufficient numbers of crystal structures of Fabs and Fvs have been determined by X-ray analyses to show that binding regions are widely diverse in size and shape. For protein antigens like lysozyme and neuraminidase, block end or shallow convex-concave types of binding seem to be favored. 'Linear' polymers like single-stranded DNA and some carbohydrates are most conveniently accommodated in large grooves in the V_L - V_H interface. Monosaccharides on branched carbohydrates and small haptent-like molecules fit into cavities or relatively small depressions on the surface of the antibody. A high-affinity site for fluorescein in the murine 4-4-20 antibody proved to be a very tight slot in the V_L - V_H interface.

Figure 4 Model of the Kol IgG1 immunoglobulin, as adapted from Marquart *et al.* (1980). The Fab arms in the hinge region are shown in the model, but the Fc region is missing because it is disordered in the crystal. Interchain disulfide bonds in the hinge region are represented by black bars. Note that the Fabs have extended structures with close interactions between V_H and V_L .

One human L chain dimer (Mcg) has a two-compartment binding region, consisting of a large conical cavity and a deep pocket. More than 60 ligands, including fluorescent compounds, dinitrophenyl and other aromatic compounds, peptides, and oligonucleotides have been found to bind in a series of subsites along the entire interface of the two V_L domains. Moreover, human and insect hormones of eight or more residues have been shown to bypass the Mcg deep pocket, force passage between the domains through an unexpected route and span the space between the conventional binding cavity and the solvent pool between the V and C domain pairs.

In many but not all of the ligands tested for binding by Fab and Fv fragments, H chain substituents, particularly those in CDR3, seem to play more important roles than those in the L chains. CDR3 of the V_H domain often occupies an inordinate amount of space between the V_H and V_L domains and is therefore more likely to come into contact with the antigen. However, the L chain contributions may also be substantial or even dominant. For example, in the case of an anti fluoresceyl antibody (4-4-20), the light chain provides five of the primary contact residues for the hapten.

Generally, the interactions stabilizing the antibody–ligand complex are mediated through the amino acid side-chains rather than the atoms along the polypeptide backbone. However, there are examples in which the carbonyl oxygen and the proton on the amide nitrogen of a peptide bond participate in hydrogen bonding interactions with hydrogen

donors or acceptors on the ligand (e.g. as occurs in a complex of an anti-single-stranded DNA antibody with its oligodeoxynucleotide). In addition to hydrogen bonding, the interactions of antibodies with ligands include the usual types associated with proteins, namely the formation of ion pairs, hydrophobic interactions, ring stacking, and other aromatic–aromatic interactions.

The hinge region

A separately encoded ‘hinge’ region is inserted between the C_H1 and C_H2 domains. Portions of the hinge regions of two human IgG1 antibodies can be seen in **Figures 3 and 4**. In the human and murine IgG1 subclasses, the initial part of the hinge region supplies the half-cysteine residue which forms the interchain disulfide bond with the L chain (see **Figure 4**). Its half-cysteine counterpart in the L chain occupies the C-terminal location in a κ chain and the penultimate position in a λ chain. Disulfide bonds linking the two heavy chains are found in a relatively rigid ‘core’ segment (Cys-Pro-Pro-Cys-Pro) of the hinge region. Segments flanking this core section are responsible for the flexibility suggested by the name ‘hinge’. Papain hydrolyzes peptide bonds among residues 6–10 of the upper flexible segment (‘proximal hinge’) between the H–H and the H–L interchain disulfide bonds to produce Fabs. Pepsin cleaves the lower flexible segment (‘distal hinge’) after the disulfide bonds to release a $(Fab')_2$ fragment.

In the most prevalent subclass (IgG1) of human

Figure 5 Model of the Mcg IgG1 myeloma protein, in which a discrete hinge region is deleted. The connecting segments between C_{H1} and C_{H2} are derived exclusively from the first seven residues of the C_{H2} gene product. Note that these connecting segments cross in the model. Because they cannot form a disulfide bond with the heavy chain, the appropriate half-cysteine residues in the two light chains form a disulfide bond across the crystallographic dyad relating the two halves of the IgG1 molecule. The shortening of the heavy chain, together with the inter-light chain disulfide bond, lead to different structural relationships between the light and heavy chains, including a very large, concave active site at the tips of the Fab arms. Note the large structural differences between the constrained Fc region in this intact IgG1 molecule and the Fc fragment released from a conventional IgG1 molecule by the action of papain (as seen in Figure 3).

IgG molecules, the hinge region typically consists of only 15 residues, while the corresponding segment in IgM and IgE molecules is sufficiently large to be considered an entire C domain. When hinge regions are present, as in the two human proteins Kol IgG1 and Zie IgG2, the Fab portions of these molecules adopt ordered structures in the crystals, while the Fc regions are 'disordered' and therefore cannot be analyzed by X-ray diffraction techniques. This causes the crystallographic structure of the intact Kol IgG1 immunoglobulin (Figure 4) to resemble a $(Fab')_2$ fragment.

In a small minority (1–2%) of IgG proteins, the hinge region is deleted from the heavy chain. These proteins (e.g. Dob, Lec and Mcg IgG1 immunoglobulins) are less flexible than molecules with hinge regions. However, the loss of flexibility appears to be advantageous for uniform packing in crystal lattices. Such proteins have therefore proved

to be favorable for X-ray crystallographic analyses. The crystal structure of the McG IgG1 immunoglobulin is shown in Figure 5.

When the hinge region is deleted, the interchain half-cysteine residue on the light chain can no longer pair with a heavy chain partner. Usually, alternative pairing is established by formation of an interchain disulfide bond with the second light chain in the antibody molecule (see Figure 5, center S–S bond). Although the effects are difficult to assess quantitatively, the formation of this disulfide bond partially restricts the freedom of the Fab arms to move independently and thus accentuates the loss of flexibility associated with a hinge deletion alone. Since the Fc region is pulled tightly up into the junction of the Fab arms, its rotational or translational mobility is also severely impaired.

Again we have an example of how the delineations of unusual features can lead to a better understanding

of the highly evolved and efficient structures of the dominant molecules in 'normal' sera. Just as the pathological effects of incomplete glycosylation focus attention on the role of carbohydrates in keeping IgG antibodies soluble, the deletion of the hinge and the formation of an L-L disulfide bond help us understand the tremendous advantages of a flexible hinge in the tracking and cross-linking of deleterious antigens.

IMMUNOLOGY, A BRIEF HISTORICAL PERSPECTIVE

Edward S Golub, Pacific Center of Ethics and Applied Biology, California, USA

Immunology as a discipline has its roots in both applied and theoretical science. It has sought practical methods of immunizing and vaccinating to prevent specific infectious disease, and an understanding of the mechanisms involved in the induction of specific immunity. This entry is not an attempt to identify and catalog specific events in the history of immunology. Rather, it describes the large trends and sets them in a historical and intellectual context. In that sense, it is an intellectual history of immunology.

One philosophical approach to the history of science as intellectual history refers to the concept of a 'paradigm'; this approach is exemplified by Kuhn's book *The Structure of Scientific Revolutions*. According to Kuhn, a paradigm is a viewpoint held by a community of scientists. Paradigms form the foundation of experimental design and, most important, of interpretation of experimental results.

Kuhn has argued that a science becomes a 'mature' science only when it has a paradigm, and that it changes only when this paradigm changes, an event that happens only rarely. When a paradigm does change, there is a revolution in the way that the relevant science views itself. I refer here to the Kuhnian notion of a paradigm because it provides an instructive perspective from which to look at the history of immunology. I am fully aware that there are other ways to look at scientific progress and change (see Lakatos and Musgrave, *Criticism and the Growth of Knowledge*).

Preparadigmatic immunology

Protoimmunology: from the ancients to the Enlightenment

The scourges of infectious diseases have declined steadily and dramatically during the last century.

During this period, modern immunology had its beginnings and immunologists, not surprisingly, tend to see a causal relation between these events. But the discipline of public health was developed before immunology and has almost certainly played a larger role in the control of infectious disease and the elevation of the lot of humankind. It can be argued that the concepts and practices of public health raised the standard of living to the point at which individuals, now aware of the value of their own lives, wanted prevention of specific diseases (see Latour, *The Pasteurization of France*).

The fact that survivors of a plague were somehow spared from dire consequences of a second encounter with the disease was well known to the ancients. Thucydides, commenting on the plague of Athens of 430 BC: 'Yet still the ones who felt most pity for the sick and the dying were those who had had the plague themselves and had recovered from it. They knew what it was like and at the same time felt themselves to be safe, for no one caught the disease twice, or, if he did, the second attack was never fatal. Such people were congratulated on all sides, and they themselves were so elated at the time of their recovery that they fondly imagined that they could never die of any other disease in the future.' (Thucydides, *The Peloponnesian War*).

The realization that the survivors of a plague having once recovered were not going to succumb to it in the future came not from experiment but from observation, as did so much understanding of the world. So, too, must have come the eventual realization that these survivors were not to be spared from other diseases in the future. But the idea of specific immunity to a specific disease was probably not yet understood. Many examples from antiquity through medieval times suggest that people were aware that they could protect themselves from disease. This 'protoimmunology', the nonscientific awareness that there could be protection to a disease, does not however seem to have played an important part in magic or religious ritual in early societies. Perhaps life was so fraught with danger from diseases of all kinds that freedom from one offered only a small respite. Another disease could strike soon; women risked dying in childbirth, men in war, and both by famine. The souls represented in a Breughel painting were not likely to have been aware of the subtle differences between one form of suffering and another. A few diseases like the black plague, smallpox and erysipelas had sufficiently distinct symptoms to stand out, but the inhabitants of early modern Europe could not distinguish easily the various forms of fevers and pestilence. Since the reason for the existence of these fevers and pestilence, often tied to

magic and religion, was thought to be Divine retribution for collective sin, many people may have concluded that this suffering was not to be alleviated.

But if 'protoimmunology' was not part of ritual, it was a part of ordinary life in some societies. The Chinese inoculated healthy people with material removed from a pustule of a person with smallpox. They 'opened the pustules of one who has the Small Pox ripe upon them and drying up the Matter with a little Cotton . . . and afterwards put it up the nostrils of thowse they would infect . . .'. Smallpox was probably introduced into Europe by both the Crusaders and the Saracens in the sixth century. It is estimated that in sixteenth-century England, only five of 1000 persons escaped infection and over half of the population had obvious pockmarks. Smallpox was not as common by the eighteenth century, but it was still a real scourge for many people. Nevertheless, it was known in that century in some circles in England that people who had been infected with cowpox did not have the pockmarks of smallpox. Edward Jenner (1749–1823), who himself had had a traumatic experience when he had been treated with pustule material as a boy, turned this bit of folklore into what perhaps became the most famous clinical trial of all time. When he suggested to a Gloucestershire milkmaid patient that she had smallpox she replied, 'I cannot take the smallpox because I had had the cowpox.' Following her lead, in May of 1796, he inoculated 8-year-old James Phipps with cowpox and then, several months later, inoculated him with smallpox. James Phipps survived and the era of safe immunization began. Jenner's paper, which was rejected by the Royal Society ('lest he damage his reputation') and published privately, made him an international hero and opened the way for people to begin to think about prevention of specific diseases.

This advance coincided with the period we term the Enlightenment: public health had made life more 'civilized' and Europeans had come to believe in the goodness and perfectibility of human beings.

The first paradigm: specific etiology and immunization

Louis Pasteur and the 'wonderful century'

The middle of the nineteenth century (the 'wonderful century') saw political and scientific ferment and the career of Louis Pasteur (1822–1895) exemplifies that ethos. Trained as a chemist, he made important contributions to structural chemistry before he turned to the question of fermentation in 1857. Fermentation was understood loosely; it referred to the 'spontaneous' changes seen in the making of wine or beer (alcoholic fermentation), the souring of milk (lactic

fermentation), etc. Putrefaction of animal tissue was thought of as another form of fermentation, one that led to noxious products. All of these were thought to be caused by chemical agents that catalyzed chemical reactions. The catalysts were called 'ferments'; yeast was the ferment known to be responsible for the production of alcohol and wine and the rising of dough. Even though Schwann and others had showed in 1837 that yeasts were living entities more closely related to plants than animals, the great chemists and their followers did not see any value in microscopic evidence. The idea that living agents were involved was relegated to 'vitalism', which was anathema at that time to great chemists like Leibig, Berzelius, Helmholtz and Wohler. They considered the yeast seen in fermentation to be chemical precipitates. The great Leibig summed up the chemists' view of a vitalistic nature of ferments: 'As to the opinion which explains the putrefaction of animal substances by the presence of microscopic animicula, it may be compared to that of a child who would explain the rapidity of the Rhine current by attributing it to the violent movement of the many millwheels at Mainz' (quoted by Dubos, *Louis Pasteur: Free Lance of Science*). Pasteur was of the chemical tradition.

Between 1855, when he first addressed the problem of lactic fermentation, and 1857 when he presented his 'Mémoire sur la fermentation appelée lactique', Pasteur had moved from the view of the chemist to that of the biologist. By 1860, he had published the 'Mémoire sur la fermentation alcoolique', which formalized the theory that different kinds of fermentations are produced by different kinds of organisms. Pasteur worked on the theoretical questions of the nature of the ferments in the very practical context of 'diseases' of fermentation. He had become a national hero for saving first the wine and then the silk industries by curing their diseases and found that the 'diseases' were caused by specific microbes. Ultimately, this was to lead him to the germ theory of disease, namely the crucial idea that each infectious disease is caused by a specific microbe.

It is important to realize the tenor of the times. Darwin had published *Origin of Species* in 1859. The hold of church and the past on the European mind was changing rapidly. In France, a great (and final) debate on the subject of the spontaneous origin of life raged and Pasteur, who never avoided a conflict, was at the center of it. His now famous swan-necked flask experiment is still used as the final argument against the idea that microbial life arises spontaneously. By 1860, the idea that specific diseases are caused by specific microbial agents which do not

arise spontaneously had been formulated and accepted.

These ideas rank in the front line of advances in intellectual history. In 1879, he made a chance discovery that, while not of the intellectual scope of the first ones, began the field of modern immunology. (It is understandable that he is also remembered for the maxim that 'chance favors the prepared mind'.) In the spring of that year, he had begun experiments on chicken cholera. After the summer vacation, it was found that the cultures of chicken cholera bacillus that had been kept during the summer did not produce disease when inoculated into chickens. A new culture was obtained from a natural outbreak and was virulent when injected into new chickens. But when these virulent cultures were injected into the animals that had not succumbed to the old cultures, the animals remained free of disease. Pasteur immediately recognized the analogy between his result and that obtained when Jenner's cowpox was found to protect against smallpox. In homage to Jenner he called the phenomenon 'vaccination' and forever enlarged the meaning of the word. With this, Pasteur established the *general* principle that an organism can be altered so that it does not cause disease, but still retains the property of inducing immunity. What had been a brilliant but apparently anecdotal clinical insight for Jenner was given a scientific basis and raised to the level of a scientific principle by Pasteur. The science of immunology was born.

Louis Pasteur established that specific diseases are caused by specific organisms that do not arise spontaneously and that they can be used to induce specific immunity. Not surprisingly, Jenner and Pasteur were both revered in their lifetimes throughout the entire world because they had fulfilled the first aim of immunology, to protect humankind from infectious disease. In our time, only Jonas Salk has attained a similar status for the very same reason.

There followed two decades of competition between the French and German schools of immunologists, headed by Pasteur and Robert Koch in Berlin. They have important implications in both the history of immunology and international relations. In this time of extreme nationalism, both Pasteur and Koch saw themselves (and were seen by their countrymen) as defenders of national honor. It is rare in the history of nations that chauvinism bears socially useful results but this was one of them. In the attempt to be the first to identify the organism responsible for every disease, and to develop a procedure to immunize against them, the French and the Germans tried to outdo each other. While neither France nor Germany was ennobled, as their fervid

citizenry had hoped, the world acquired, along with war, hardship and hatred, the means of inducing specific immunity to many diseases and we began to understand the mechanism of this immunity.

One very important realization was that the mechanism of the immune response toward an innocuous substance, such as a foreign erythrocyte, was the same as that against a deadly bacillus. Thus it became possible to study immunology using surrogate pathogens. If this were not true, and if it had not been realized early in the history of the science, the enormous progress that has been made in understanding the mechanisms of immunity might not have been possible.

The second paradigm: clonal selection

Ehrlich, Haurowitz, Jerne and Burnet: the path to clonal selection

The path from Jenner to Pasteur established immunology as a mature science because it led to the first paradigm of immunology, namely that it is possible to inject altered forms of organisms to induce specific immunity. The next paradigm to be established, *clonal selection*, made it possible to study the mechanisms of immunity. The principle of clonal selection is that each of the cells involved in the immune response (the lymphocytes) are preprogrammed to express receptors and to respond to a single antigenic determinant. When antigen is introduced into the system it is processed and reacts with the receptor, inducing the cell to proliferate. Antigen thus acts as a selective agent in the Darwinian sense; the cell is induced to proliferate and undergoes clonal expansion, resulting in many more cells of the same specificity. The path to this idea began with Paul Ehrlich (1854–1915) in his Croonian Lecture to the Royal Society in 1901, which appears to be the first attempt to explain the observations of Jenner and Pasteur.

Ehrlich, in that lecture, postulated that the cells responsible for antibody production have *side-chains* on their surfaces, each of which have the ability to react with a single disease-causing entity. In Ehrlich's view, the reaction of a microbe or toxoid with the appropriate side-chain caused the cell to produce more of that side-chain so that soon the entire surface of the cell was covered with molecules of this specificity. In fact, the cell was thought to overproduce them and the excess appeared in the serum as antibodies. This first modern theory of antibody production is of a type we now call *selection* theories, because it postulates that the receptors (side-chains) are already present when the antigen is introduced and the role of the antigen is to select the side-chain.

The startling prescience of this idea that runs so counter to intuition cannot be overstated.

The side-chain theory stood until the 1930s when Karl Landsteiner (1868–1943) began his famous experiments on haptens and carriers. Landsteiner showed that when small molecules that by themselves were not able to induce an antibody response were conjugated to large immunogenic molecules, an animal was able to make an antibody response to them. The large molecule acted as a *carrier* and the small molecule that had become immunogenic by coupling to the carrier was called a *hapten*. Landsteiner showed that the antibodies produced to dinitrophenyl, for example, were specific for that hapten and did not react with antibodies raised to trinitrophenyl. In his influential book *The Specificity of Serological Reactions*, he attempted to develop the rules for immunogenicity. This attempt was not successful, but what did emerge was the fact that he could synthesize a seemingly endless array of substituted molecules, each of which gave rise to a specific antibody response. There could not be enough room on the surface of a cell for all of the side-chains that Ehrlich's theory had postulated. The scene was set for a change of paradigm and this was provided by Felix Haurowitz.

Haurowitz (1896–1988) was a German living in Prague. A physician, he was trained as a physical biochemist and had earned a reputation for his work on the structural forms of hemoglobin. A colleague, Breinl, who had spent a year at the Rockefeller Institute in New York, told him of Landsteiner's work and he and Breinl designed an experiment to determine the amino acid composition of gamma globulin before and after immunization. Using the methods available in 1930, they found that the amino acid composition was the same in both cases and concluded that since the quantity of each amino acid was the same, the *order* had to be different between non-immune and immune globulin. This conclusion led them to the theory that became known as the *template theory* of antibody formation. It postulates that a fragment of the antigen enters the antibody-producing cell and there acts as a template that directs the order of the placing of the amino acids into the protein. A positive-charged amino acid in the antigen fragment results in a negatively charged amino acid in the antibody molecule and vice versa. This theory is a fundamental departure from the selection type of theory of Ehrlich because instead of the antibody-forming cell being preprogrammed to produce antibody, in this theory the antigen is instructing the cell what antibody to make. It is an *instructive-type* theory of antibody formation.

Between 1931 when it appeared (Linus Pauling

expanded on the idea in an influential series of papers in the 1940s) and the 1950s when it was seen to be untenable, the direct template theory was appealing because it made sense and was testable. With the discoveries of the 1950s leading to the new genetics based on the 'trinity' of DNA–RNA–protein, the template theory of antibody formation was abandoned. It is one of history's small ironies that James Watson, the codiscoverer of the double helix and one of the founders of the new genetics, as a graduate student at Indiana University was a student in Haurowitz's class in biochemistry.

The template theory was replaced by another version of a selective theory by Neils Jerne (b. 1911). Jerne, a Danish polymath, was an immunologist at the Danish Serum Institute in Copenhagen but spent his summers as part of the famous 'phage group' of Max Delbrück at Caltech. These ideas were based largely on the 'Luria–Delbrück' experiment that showed that mutations are random events and not induced by the selective agent, i.e. the agent selects the mutant, it does not induce the mutation. In 1955, building on the theory of the phage group, Jerne proposed a new version of the original selective-type theory. This theory, called the *natural selection theory* of antibody formation, was based on his observations that all animals have detectable levels of antibody to a wide array of antigens in their serum even though they have never been intentionally immunized to them. His theory stated that, upon entering the system, antigen reacts with these 'natural antibody' molecules and the complex of antigen and antibody is transported to a cell and internalized, causing the cell to produce more antibody. F. M. Burnet (later Sir Macfarlane Burnet) suggested that the theory would be improved by having the antigen react at the surface of the cell rather than be internalized. The idea was thus changed to have the unit of selection become the receptor on a preprogrammed cell rather than the antibody in the serum. It was parsimonious to assume that the receptor was an antibody molecule of the specificity that the cell was preprogrammed to make. The theory stated that the reaction of antigen with cell surface antibody receptor induced the cells to proliferate, resulting in a clonal expansion of cells. Hence the theory was called the *clonal selection theory*.

The clonal selection theory was very quickly championed by a prominent immunologist, David Talmage, and by the Nobel prize-winning geneticist Joshua Lederberg. The theory appealed to both communities because it appeared at the time when genetics was establishing the basis of the modern era of biology and it served to bring immunology into the mainstream of biology and genetics. Within a short

time, both Haurowitz and Pauling conceded that the instructive-type theories were no longer tenable. Even though clonal selection was counter to the intuitive view that workers in the field had at the time because of decades of experimental evidence being interpreted through an instruction-type lens, it fulfilled Kuhn's description of scientific revolutions; when it was accepted, it was accepted totally.

Immunology now had its second major paradigm and the field changed dramatically from descriptive serology to one more closely related to cell biology because the intellectual groundwork had been laid to study the unit of selection, the preprogrammed cell. The questions that immunologists could now address were the cellular basis of the immune response and how the genes that encode the antibodies are organized. The stage was set for the cellular and molecular era.

The modern era: cellular and molecular immunology

With the establishment of clonal selection as the dominant paradigm, the framework was in place to attempt to explain the phenomena of the immune response. The problem was threefold:

1. What is the structure of the antibody molecule and how could the genes for molecules that react with an enormous number of antigens be organized?
2. What is the cellular basis for the immune response?
3. How is the system regulated (including the question of self/nonself discrimination)?

The great advances in the last three decades comprise the bulk of the entries in this encyclopedia and attest to the great progress that has been made in addressing the questions of mechanisms. The merging of molecular biology and immunology, along with giving us the tools to study the mechanisms, have allowed new approaches to vaccine development to occur and the promise of the next decade is the application of these great advances to the betterment of the human condition.

IMMUNOPATHOLOGY

David R Katz, Department of Immunology, University College London Medical School, London, UK

There are three ways in which the term 'immunopathology' has been adopted as a useful descriptive term:

1. Several immunological processes can be regarded as representative of normal 'immunophysiology'. In this framework, immunopathology is any process in which the physiological mechanism is damaged.
2. Rapid advances in immunology over the past 30 years have made a significant impact not only in our understanding of the immune response itself, but also in providing many of the modern technologies which are now applied to the study of pathological processes in general. Thus, in this framework, immunopathology is the discipline which is involved in studying disease processes using immunological methods; and the person who does this kind of investigation is the immunopathologist.
3. Although the immune response has evolved as part of the response to injury, it is now widely recognized that in several instances it is the response itself that is in fact what is recognised as characteristic of the disease. This form of immune injury is thus regarded as immunopathology.

Immunophysiology and immunopathology

The physiology of the immune system has to encompass the capacity of the cells that constitute it to respond to a wide range of exogenous stimuli, and

the capacity to operate under diverse conditions at the periphery as well as in central sites.

An attractive hypothesis is that the difference between immunophysiology and immunopathology should be regarded in evolutionary terms. In this hypothesis, a unicellular organism will respond to an exogenous stimulus (such as cell-cell contact) with a physiological reaction (such as repulsion and phagocytosis). As soon as multicellularity arises, there must be some mechanism to recognize the second cell as self, and hence not a potential target – but this mechanism must make use of the existing recognition pathways to generate such a 'nonresponse'. As soon as this nonresponse to self condition has been achieved, the organism has created for itself a new homeostatic status, which can be maintained and regulated as the molecules concerned turn over and are replaced, but which becomes the physiological immune system for that particular organism.

Subsequently, added on to this very basic recognition mechanism, as the immune system has evolved, we have acquired overlays, so that in mammals there is a complex pattern of genes which have the potential to rearrange and encode for proteins specific for target antigens. If the target is a self product, then these genes may rearrange to encode for the proteins that are involved in positive and negative selection in the thymus, as examples of immunophysiologic reactions. If, on the other hand, the target is extrinsic, then the rearrangement is not immunophysiologic.

In this context, the major type of immunopathology is clearly breach of tolerance to self. Although

this is the most obvious and well-established example, it is not difficult to envisage how other instances might arise. For example, most cytokines have been identified for their role in response to injury and in pathological processes. Presumably, these roles represent immunopathology, and the mediators do have a physiological homeostatic role which has thus far been much more difficult to define.

The use of immunological techniques in the study of disease

Traditionally, the basis for this 'investigative immunopathology' is serology. Detection of antibody against a specific pathogen, and of rising (or falling) titers of antibody, has long been the mainstay of the approach. The concept of autoimmunity is heavily based upon the identification of circulating antibodies directed against intrinsic antigens, and there is also reciprocal serology, based upon the use of antisera to detect a given antigen.

There are now many ways to detect and amplify the signal given in serology-based assays. The use of complement fixation to detect the formation of complexes was an early example; and there are now a host of other similar procedures, many of which rely on a second superimposed antigen-antibody reaction, or upon a combination of antibody with biotin, which can then be identified using an avidin-coupled detection system. Enzyme-linked antibody in ELISA assays has been used either alone or in conjunction with biotin-avidin and has proven a useful and efficient alternative to isotope. The most significant development in serology-based studies has undoubtedly been the advent of monoclonal antibodies, which have made a considerable impact upon the specificity that can be achieved.

In a sense, most of the other techniques that are used in investigative immunopathology are extensions of the serological approach. These methods have been used to purify proteins by affinity, and have also been used in more sensitive detection systems such as western blotting. Furthermore, serology is also the basis for studies that are orientated toward cells and tissues. Thus antibodies are used as the detection system for different cell types, both for the immune cells themselves (such as the lymphocyte subsets) and for other cells in epithelial and connective tissues.

Immunofluorescence, where an antibody is coupled to a fluorescent dye can be used in several different ways: for fluorocytometry (including preparative sorting), for detection of antibodies directed against cellular targets in autoimmunity, and for

both detection and isotyping of immune complex deposits. In histological examination of tissues, immunostaining methods, where the detection is via either peroxidase or alkaline phosphatase, have formed the basis for re-evaluation of previous tumor classification, and have made quantitative analysis possible. There are difficulties in this approach, in particular those related to the preservation of the antigen (in terms of accessibility, structure and configuration) under fixation conditions; but there are also unique advantages, since immunopathologic methods can be used in this context not only as cell detectors, but also to monitor cell function, where the antibody may be directed against cell cycle-related proteins, or against growth factors and their receptors.

Recently, immunopathology has also provided powerful adjunct techniques for molecular pathology, where the *in vitro* translation products of specific genes have been characterized using monoclonal antibodies; and, conversely, expression vector libraries have been generated which can be used to screen for identification of the gene which encodes for a particular protein.

However, investigative immunopathology is not confined to the study of antibody. Analysis of the complement components *per se* may also be used to monitor disease, either involving the complement system itself or as a marker of complex formation. Quantitative cellular studies are useful, and thus far have proven more reproducible than any of the functional immunopathological assays (such as phagocytosis, chemotaxis, natural killer activity, cytotoxicity, and alloresponses) that have been used as research tools to examine disease. Strictly, blood group serology and HLA typing are not classifiable as immunopathologic methods, since they document physiological markers rather than disease states, but both have been used to determine disease associations.

This armamentarium of procedures has provided the opportunity for investigating disease in many different ways, some of which have been mentioned already. It is probably true today that even if at a superficial level there is no obvious connection between a particular disease process and the immune system, in every instance there will be at least one investigative procedure which falls within the remit of immunopathological analysis.

Immunological mechanisms as pathologic processes

The assumption is generally made that the immune response is protective. To appreciate the concept of

immunologic mechanisms as pathologic processes, the paradigm of the immune system as a beneficial event has to be shifted completely.

There are some situations where the actual lesion is a relatively localized interaction between cell-cell and cell-organism. Perhaps the classic example is that of the most commonly recognized form of *Mycobacterium tuberculosis* infection, where a relatively minute area with only one or two bacilli is identifiable in the tissue lesions. However, it is the tissue response to these localized interactions that is so extensive and is what is in fact recognized as the disease. To continue the example: the extensive granuloma formation is itself what is destructive and spreading into surrounding tissues, and it is this reaction that is recognized as the immunopathology.

In these instances, where the disease itself can be regarded as immunopathologic, the initiating agent may no longer be identified, but nonetheless the ongoing processes are frequently destructive and may be life-threatening. Perhaps the hallmark of such processes is in fact that they readily become self-perpetuating, i.e. the immunologic cascade has been initiated and continues to generate further tissue damage way beyond the original insult.

Immunopathology in this context is thus very closely linked to the classic four patterns of tissue injury (hypersensitivity reactions) that have been described in the literature. Like these four reactions, there are often extrinsic antigens which cause the disease process, but autologous antigens often play either a primary or perpetuating role.

Although type I anaphylactic reactions have their own distinctive features, they are rapidly developing immunologic reactions which occur in minutes and long-standing changes such as tissue destruction are usually not a feature. These are the forms of tissue injury where IgE synthesis is the key component, and the immunopathologic process is recognized when there is perpetuation of the process with basophils and mast cells predominating.

In many cytotoxic reactions, such as transfusion and hemolysis, the clinical emphasis is usually placed upon the circulating components, but the immunopathologic event itself is the synthesis of antibody which destroys a self component present on the surface of the target cell. This component may be either autologous or extrinsic, such as when drugs are coupled to red cells. The immunologic events which follow include complement activation and target cell lysis.

Variants of the cytotoxic form of immunopathology include where the antibody is against a receptor, blocking ligand-receptor interaction. This may have the same consequences as lysis of target (i.e.

nonfunction), even though the receptor-bearing cell remains alive. Perhaps the best characterized example of this type of immunopathologic event is the synthesis of antibodies to the acetylcholine receptor, which is the cause of impaired neuromuscular transmission and hence muscle weakness in myasthenia gravis.

The other well-established variant is when antibodies are directed against connective tissue components such as basement membrane. The disease which is perhaps the best-known example of an immunopathologic process, where the primary injury is not known but the mechanism is immunologically mediated, is Goodpasture's syndrome. Antibasement membrane antibodies bind directly and block function to give linear glomerular deposits and also involve the alveolar wall interface with lung capillaries. That the lesion is immunopathologic has been confirmed by remission induction using plasmapheresis.

Immune complex formation leads to several different types of immunopathology. At a basic level, the question is really not why immune complexes constitute such an important component in immunopathologic processes, but rather what are the factors that make these particular immune complex patterns pathologic, whereas most immune complex formation is by definition a successful form of host defense.

Immune complex formation can be localized (as in an Arthus reaction) or systemic. The tissue hallmark is commonly a vasculitis, and this vasculitis may occur in many different sites: arthritis, endocarditis, glomerulonephritis and alveolitis are all possible. The nature of the complex varies, depending on whether the antigen is endogenous or exogenous, and on whether the immunopathologic event is the formation of a complex *per se*, as in lupus erythematosus, or of a complex of antigen, antibody and anti-antibody, as seen in rheumatoid arthritis.

The immunopathogenetic mechanism in immune complex disease starts as an acute local inflammatory reaction in response to the presence of the complex, but the key event is probably complement activation and fixation. Serum complement levels fall due to 'consumption' by complexes and neutrophils are attracted to the site. The natural history of the disease varies, but is again commonly persistent and chronic.

The granulomatous form of immunopathology has already been mentioned. These cell-mediated events are often a reflection of a classic delayed-type hypersensitivity and are the most obvious example of how a response can itself become the disease. Leprosy, with destructive paucibacillary disease, may be even more dramatic than tuberculosis, with nerve damage

due to the aggressive nature of the immunopathology. There is a cascade effect in which lymphocytes play a role. Necrosis occurs as a frequent concomitant of granulomas, and is a key immunopathologic change, since by definition it is a destructive rather than reparative event.

Recent developments in immunopathology

Many of the earlier descriptive reports about immunopathology anteceded the advent of recombinant DNA technology. As in most other areas of immunology, these methods now allow for a different approach to earlier questions in this field.

One change is that with the availability of recombinant cytokines, the role of these molecules has been recognized increasingly as mediators of immunopathologic events. For example, circulating recombinant tumor necrosis factor can cause widespread tissue damage; and local injection of recombinant interferon γ modifies the immunopathology of cutaneous leishmaniasis. Another is that the role of T cell immunopathology – cytotoxic events as a cause of damage rather than elimination of infected cells – has been increasingly recognized. Likewise, failure to induce a response (i.e. failure at the level of presentation) has been identified as a more significant form of immunopathology than was previously appreciated, based upon the experience with the acquired immune deficiency syndrome (AIDS).

Most recently, there has also been increasing awareness that the immunopathologic processes implicated in a particular disease may not involve a particular gene that encodes for a particular product, such as immunoglobulin. Rather, there may be dysregulation at the molecular level, via a controlling enhancer or suppressor sequence. It is from such concepts that the molecular immunopathology of the future is likely to develop.

IMMUNOPOTENTIATION

Paul Gatenby, Canberra Clinical School, University of Sydney, Australia

Immunopotential can be defined as a process that directly enhances one or more specific immune functions, or modifies one or more components of the complex immunoregulatory network to achieve its effects through indirect mechanisms. An enormous array of crude biological extracts, plant and animal

substances of varying degrees of purity, synthetic chemicals, and now cloned cytokines and highly purified immunoglobulins have been used as immunopotentiating agents. The subject includes both immunotherapy, directed at pathogenic microorganisms, malignant cells, immunodeficiency, and the immuno-

regulatory disturbances of autoimmune disease and the enhancement of immune responses during immunization, or the use of immunological adjuvants. There is a substantial overlap between the types of substances used for both these purposes and there may well be a parallel overlap in the mechanisms involved.

The idea of stimulating the immune system to tip the balance of the struggle between an invading pathogen or malignant cell and host is almost as old as ideas that have evolved this century about the components and function of the system itself. In 1902, a series of patients were vaccinated with a cancer cell extract by von Heyden and Blumenthal. The use of adjuvants has a long history too, with Pasteur and Joubert noting in 1877 that mixing additional substances with antigen intensified the immune response. Despite this long history, the mechanisms whereby the bulk of immunopotentiators mediate their action is not clear.

Unfortunately, it is pertinent to ask why there has been so little to show in real terms from the enormous effort put into examining the mechanisms and efficacy of immunopotentiating substances. In part, this is due to the complexity of the system that is being manipulated, but much of the lack of success may be due to an overoptimistic appraisal of the role the immune system plays in neoplasia and consequent unrealistic expectations about the potential for immunotherapy of cancer. Infectious diseases, many of them of profound importance in the developing world, may have much greater potential for immunorestorative therapy than cancer. In contrast to cancer, it is fairly clear that the immune system recognizes pathogenic organisms, even if in many cases it alone proves insufficient to rid the host of the invader. Autoimmune diseases at least represent one area where there has been some progress.

Classification of immunopotentialiation

It is possible to classify immunopotentialiation in a number of ways, and one such is shown in Table 1. There is some overlap between the different categories used and the classification should be viewed as a framework within which to base discussion. In addition, combinations of specific and nonspecific mechanisms are used, such as the addition of adjuvants to specific antigens in many vaccination protocols.

Specific mechanisms

Active specific immunopotentialiation

Vaccination Prophylactic vaccination against infectious diseases remains the single most clear-cut

Table 1 Classification of immunopotentiating procedures

<i>Specific mechanisms</i>	
Active	Vaccination
Passive	Xenogenic antibody therapy Hyperimmune globulin
Adoptive	Activated (sensitized) lymphocytes – allogeneic, xenogeneic or autologous Tumor-infiltrating lymphocytes (TIL) Lymphocyte extracts – transfer factor, immune RNA
<i>Nonspecific mechanisms</i>	
Active	Immunopotentiators of biological origin Thymic extracts and synthetic analogs Cytokines Synthetic chemicals
Passive	Immunoglobulin therapy (immune serum globulin, ISG) Plasmapheresis
Adoptive	Lymphokine-activated killer (LAK) cells

success of immunopotentialiation in the practical application of immunological principles to the improvement of human and animal health. Specific vaccination has also been used to treat a restricted number of chronic infectious diseases whose response to antimicrobial chemotherapy remains suboptimal. Two examples of this are the use of vaccination with killed *Leishmania* promastigotes and live BCG as an adjuvant in the therapy of localized cutaneous leishmaniasis. A randomized trial has shown that this regimen compares very favorably to standard antimonial chemotherapy in terms of efficacy, side-effects, and cost. A similar vaccination protocol in leprosy, involving the use of killed *Mycobacterium leprae* and live BCG as an adjuvant has resulted in conversion of 85% of borderline leprosy and 65% of polar lepromatous leprosy to the tuberculoid end of the disease spectrum. These clinical observations have been accompanied by histopathological and immunological changes and, it is hoped, the patients treated in this manner will become more responsive to antimicrobial agents. Such an approach may well be applicable to other chronic infectious diseases where cell-mediated immunity is critical for resistance.

These definitive and very encouraging results have not been accompanied by similar findings from a large number of therapeutic vaccination trials with alleged tumor antigens and a variety of adjuvants in malignant disease. Probably because there is little evidence for immunogenetic tumor-associated antigens in most human neoplasias, minimal practical success has been achieved with this approach. However, in veterinary practice it has proved possible to treat certain virus-induced tumors, such as bovine

fibropapilloma, by vaccination. Powerful effects of peptide immunization have been observed in tumor models, and pilot studies in human melanoma are underway. The presumed mechanism is the selective activation by vaccination of CD8 cytotoxic T lymphocytes (CTL).

Vaccination against recurrent miscarriage One specific form of active vaccination worthy of mention is the use of paternal or mixed allogeneic white blood cells or peripheral blood mononuclear leukocytes (PBMLs) in the treatment of what is termed 'allo-immune' pregnancy failure. It is believed that some women fail to make the normal immune recognition of paternal antigens to which bearing a fetus exposes them. This failure of recognition in turn results in a failure to develop specific protective mechanisms and the fetus is lost. The ill-defined deficiency can be overcome by prior immunization with paternal or mixed allogeneic cells, or some other source of alloantigens. The procedure is still one of some controversy, although efficacy has been demonstrated in a meta-analysis. The mechanism whereby a pregnancy survives what should be a hostile immune environment is still not understood.

Passive specific immunopotentialiation

Xenogeneic antibody therapy The administration of antibodies prepared by immunizing other species, initially large animals, but more recently rats and mice, combined with immortalization of the antibody-forming cells to produce monoclonal antibodies (mAbs), have proved/or promises to be an important part of immunopotentialiation therapy. Thus diphtheria and tetanus antitoxins prepared in horses or cattle were successful adjuncts to standard therapy in the early decades of this century. This approach has, of course, been replaced by widespread vaccination of the population and the preparation of human hyperimmune serum in the case of tetanus. Xenogeneic antibodies prepared in similar ways are widely used for the treatment of envenomation from a variety of poisonous species, especially snakes and spiders.

More recently, attempts have been made to use mAbs as therapeutic agents. Some success has been achieved with mAbs directed against lymphocyte determinants found on a variety of leukemias or lymphomas, although long lasting control has not been achieved. mAbs that react with certain infectious agents such as cytomegalovirus (CMV) have also been prepared, although their role remains to be defined. The major drawback to the use of xenoantisera is the development of anti-immunoglobulins in the recipient. Such antibodies may be associated with

serum sickness which precludes further therapy. In addition, although the side-effects with mAbs seem to be less severe, the antimouse/rat antibodies rapidly neutralize the potentially therapeutic mAb, curtailing the value of therapy. The inability to use repeated doses of antibody is thus the major limitation of this therapy. This is generally not a problem with antivenins but has so interfered with mAb therapy for tumors and graft rejection that it has led to attempts to make human mAbs and the successful 'humanization' of rodent mAbs by genetic engineering techniques. The latter process has given rise to a series of potentially useful therapeutic agents directed against important surface molecules such as CD4 and CDw52, and against cytokines such as TNF α . The ultimate aim of CD4 antibodies is eventually to induce tolerance, successful to date in rodent models, but not in humans. Anti-TNF α has proved a useful adjunct to the treatment of refractory rheumatoid arthritis (RA) and its use in combination with other approaches is being explored. The use of mAbs in this way is really a form of immunosuppression rather than immunopotentialiation but has been included here for completeness.

Hyperimmune globulin therapy For a restricted number of infectious diseases, we are fortunate enough to have high-titer antibodies prepared from pooled human blood collections. Such immune serum globulins (ISG) include those with specificity for hepatitis B, vaccinia, varicella, tetanus and rabies. The antibodies are logistically difficult to obtain, expensive to prepare and maintain, and may in part be replaced by intravenous immunoglobulins that are now more widely available with better characterized antibody specificity. Not all of these specific antibodies are readily available in all countries. Anti-D postexposure prophylaxis represents a special case of successful passive specific immunization. To prevent the occurrence of rhesus (Rh) antigen-associated hemolytic disease of the newborn, Rh-negative women who deliver an Rh-positive infant or who have a spontaneous or induced abortion receive anti-D immunoglobulin. The mechanism of inhibition of antibody synthesis is not clear, but rapid clearance and destruction of Rh-positive cells from the circulation seems to play a role.

Adoptive specific immunopotentialiation

Lymphocytes A number of experimental models exist that allow the transfer of 'sensitized' or activated lymphocytes which then have a therapeutic effect against tumors with shared antigens. Similar approaches have been tried in humans generally without consistent success. The development of

cloned interleukin 2 (IL-2) has allowed expansion and activation of cells from the peripheral blood into lymphocyte-activated killer (LAK) cells. There is no evidence for *antigenic* specificity and this mechanism will be considered below. However, there is a variant of this procedure involving the expansion of tumor infiltrating lymphocytes (TILs). It is possible to expand a small number of lymphocytes up to 10^{11} cells. Their specificity, if indeed they are specific, is unknown, and early clinical studies in both renal carcinoma and melanoma have not been as promising as was hoped. Lymphocytes from regional nodes are also being used as a source of 'specific' CTL for adoptive immunotherapy. This type of therapy has yet to be tried in situations other than neoplasia.

Transfer factor In the mid-1950s, Lawrence first reported that delayed-type hypersensitivity (DTH) could be passively transferred using dialyzable extracts of leukocytes obtained from skin test-positive, normal human donors to previously skin test-negative normal human recipients. Since then, transfer factor has been widely used, particularly in infectious diseases in which cell-mediated immune responses have been felt to be defective, such as chronic mucocutaneous candidiasis, vaccinia gangrenosum, and some mycobacterial infections. Despite this, it has not yet been completely characterized and the question of its efficacy and specificity remains. It is thought to be a mixture of purine- and pyrimidine-containing polynucleotides with some polypeptide moieties. How these proposed structures carry antigenic specificity is unclear. A very limited number of controlled trials support its efficacy, but these remain largely unconfirmed and its ongoing therapeutic role is questionable now that other low molecular weight potentiators like the cytokines are available in purified form.

Nonspecific mechanisms

Active nonspecific immunopotentialiation

Immunomodulators of biological origin A summary of the different categories of substances that have been used is shown in Table 2. This represents a small sample of a vast array, with an attempt made to select the more promising. In general terms, these agents have been used both as adjuvants in vaccination procedures and as immunotherapeutic tools for neoplasms and to a lesser extent infectious disease. Little is known about the specific mechanism(s) by which these compounds exert their effect.

Many studies tend to describe one or more effector cell read-outs which shed little light on the cell inter-

Table 2 Immunopotentiators of biological origin

<i>Mycobacteria and derivatives</i>
BCG
Complete/incomplete Freund's adjuvant
Methanol-extractable residue (MER) of BCG
Muramyl dipeptides
<i>Bacterial lipopolysaccharide (LPS) endotoxins</i>
Monophosphoryl lipid A
Lipid A analogs
<i>Fungal glycans</i>
Glucan
Lentinan
Krestin
<i>Polymeric microbially derived agents</i>
Polynucleotides
Maleic vinyl ether
<i>Miscellaneous</i>
<i>Corynebacterium parvum</i>
<i>Bordetella pertussis</i>
'Picibanil' – extract of <i>Streptococcus pyogenes</i>
'Biotin' – extract of <i>Klebsiella pneumoniae</i>
'Broncho-Vaxom' – extract of eight strains of bacteria

action involved. Some agents, such as those derived from lipopolysaccharide (LPS), seem to bind to CD14, an activation ligand on the surface of macrophages. Fungal glycans activate macrophages and induce the release of interleukin 1 (IL-1), tumor necrosis factor α (TNF α) and colony-stimulating factors. Mycobacterial-derived products probably have similar actions and the polymeric microbially-derived agents are interferon inducers. These agents almost all certainly have multiple effects and an attractive unifying concept is that their cellular effects may depend on their capacity to elicit the production and secretion of cytokines (e.g. IL-1, IL-2, TNF α and interferon γ) which are the direct cellular regulatory factors. The differences between the actions of various stimulatory biological products may therefore be related to minor variations in the production of different cytokines. Adjuvants including mineral oil or mineral salts have the additional effect of holding specific antigen within the vaccine in a depot to encourage slow release over a prolonged period resulting in a more sustained immune response.

These substances have primarily been used as immunotherapy for a wide variety of neoplasms in animals and in humans. Such therapy has been combined with proposed tumor-specific antigens or made part of a multimodality approach to cancer including surgery, chemotherapy and radiotherapy. Although there have been occasional reports that deserve the accompanying enthusiasm, in general the use of immunomodulators of biological origin in human cancer has proved disappointing. Currently local

BCG is used as adjunctive therapy in bladder cancer and a variety of products are used in gastric cancer, particularly in Japan. Biostin and Broncho-Vaxom are used in chronic bacterial infections. Indeed, although much of the emphasis to date has been on cancer therapy, the place of these agents may well be as safe adjuncts in chronic infectious diseases.

Following the observation that type 1 diabetes-prone NOD (non-obese diabetic) mice raised in non-specific pathogen-free (non-SPF) conditions had a lower incidence of diabetes, NOD mice were exposed to BCG and again the incidence of autoimmunity was diminished. Although this is not a general phenomenon in autoimmune disease, these findings have led to BCG trials in identified high-risk relatives of patients with diabetes with early results pointing to a modest prolongation of the 'honeymoon' (i.e. remission) period.

Thymosin and other hormone-like factors extracted from thymus glands There are a large number of compounds that come under this heading, many with quite a substantial body of literature describing their actions. Only those that have been recently used, largely in Europe, are listed below:

- Thyostimulin
- Thymomodulin
- T-activin
- Thym-uvoval.

As well as the extracted substances, there are synthetic 'hormones' such as thymosin α 1, thymulin and thymopentin (TP5). The latter pentapeptide corresponds to amino acid residues 32–36 of thymopoietin 2 and retains the biological activity of the parent compound.

The rationale behind the use of these compounds is to accelerate the maturation of T cells from precursor cells. Most work has aimed at increasing host resistance in cancer, particularly in overcoming the immunosuppressive effects of chemotherapy, radiotherapy, surgery or the tumor itself. Minor improvements in survival have been reported with some of the compounds listed, but no clearly defined role in antineoplastic therapy exists. Thymic hormones, particularly thymosin fraction 5, thymosin α 1 and TP5 have been used in children with primary immunodeficiency diseases such as the DiGeorge syndrome, chronic mucocutaneous candidiasis, the Wiskott–Aldrich syndrome, and other immunodeficiencies associated with thymic hypoplasia or dysplasia. In recent years these substances have been widely used in acquired immune deficiency syndrome (AIDS). There is little reproducible evidence of sustained benefit. These substances have also been used

to treat a number of autoimmune diseases, especially systemic lupus erythematosus (SLE) and rheumatoid arthritis (RA). The aim has been to reverse the immune imbalance believed to be associated with the disease process. The results, however, have been disappointing and none of these agents has secured a regular place in therapy. In a sense, this is hardly surprising as the physiological role of these compounds, extracted or synthetic, in normal T cell maturation in the thymus is far from clear.

Cytokines and other biological mediators The ability to produce a wide array of biological mediators by recombinant DNA techniques has allowed an enthusiastic expansion of biological response modifier (BRM) programs. Some of the substances discussed have been used therapeutically for several years, others at this time are little more than interesting compounds to investigate.

Cytokines that have been widely used are shown in Table 3, where they have been grouped into those with clearly defined functions and those in which early study looks promising. A fundamental problem with most cytokines as therapeutic agents stems from the fact that relatively large doses given systemically have many, generally proinflammatory, side-effects. Ultimately, agents derived from cytokines that act more exclusively on particular receptors may be of more use.

Table 3 Therapeutic use of cytokines

<i>Proven or widespread use</i>	
Interferon α	
	Hepatitis C, hepatitis B
	Papilloma virus (local)
	Hairy cell leukemia
	Multiple myeloma – a small response rate and maintenance of plateau phase
	Kaposi's sarcoma with HIV infection and a reasonably preserved CD4 count ($\geq 200/\mu\text{l}$)
	CML in chronic phase
Interferon β	
	Multiple sclerosis
Interferon γ	
	Chronic granulomatous disease
	Visceral leishmaniasis
<i>Early study looks promising</i>	
Interleukin 2	
	Rare cases of severe combined immunodeficiency (SCID) with IL-2 deficiency
	Metastatic renal carcinoma
	Melanoma ?
IL-2 with antivirals in HIV infection	
IFN γ to reduce a T $_H$ 2 response, e.g. severe atopy	
IL-10 – may be useful to enhance a T $_H$ 2 response	
IL-12 – may be useful to enhance a T $_H$ 1 response	

Synthetic chemicals (thymomimetic drugs) To date, the best characterized examples are levamisole, isoprinosine, ditiocarb, methyl inosine monophosphate (MIMP), azimexon and imexon. The mechanisms of action are not very clear but possibly include the induction of thymic hormones, possession of thymic hormone-like properties, and in most cases direct effects on phagocytic and perhaps natural killer (NK) cells.

Levamisole was first used as an immunopotentiating agent in 1971 and is considered to be capable of restoring defective cell-mediated immunity (CMI), but does not affect normal CMI. Lymphocytes, granulocytes and macrophages are all stimulated. Levamisole has been tried in a wide array of disease states, ranging from cancer and infections to autoimmune diseases. Overall, the effects have been disappointing and the side-effects considerable. It may find a substantive role in the treatment of large bowel cancer in conjunction with cytotoxic drugs.

Isoprinosine is thought to act through a receptor for an inosine-like compound on T cell precursors. *In vivo* it appears to induce the production of more mature T cells and there is some evidence that it can increase the CD4:CD8 ratio in a variety of conditions. It has been demonstrated to ameliorate a number of viral infections, particularly acute and recurrent herpes simplex virus, rhinovirus, and appears to be able to arrest the progress of measles-related subacute sclerosing panencephalitis. It has the advantage over levamisole of very few side-effects. Some data suggest an improvement in indices of CMI in patients with early HIV infection. Whether this is accompanied by any useful clinical effects is not clear. Overall, the effects are not very impressive, although it has achieved licensing for some of the above in many countries.

The other agents have largely been spawned from desperate attempts to find compounds that will impede the progressive immunodeficiency of HIV infection. To date, little success has been reported.

Passive nonspecific immunopotentialiation

Immunoglobulin therapy Although specific immune serum globulins (ISG) (as described above) and polyvalent ISG have been available for several decades, it was only with the purification of immunoglobulin G (IgG) in such a way that high-quality preparations suitable for larger-dose intravenous infusion were obtained that manipulation of the immune system with these agents became realistic. An important use remains antibody replacement in individuals with primary hypogammaglobulinemia. Intravenous immunoglobulins have also been used as an adjunct to standard antimicrobial therapy in severe bacterial

infections. At first sight, it would seem clear that this should be a useful maneuver, but in fact the data are far from clear-cut and will really only be settled by randomized controlled trials. High-dose polyvalent ISG has been used successfully for prophylaxis of cytomegalovirus (CMV) and to a lesser extent varicella zoster virus in immunocompromized patients.

The most interesting new role for high-dose polyvalent ISG has been in a variety of autoimmune diseases where perhaps there is an immunoregulatory disturbance corrected by the immunoglobulins. The mode of action is not well understood; if elucidated, it will undoubtedly expand our knowledge of the complex interactions of antibodies, antibody synthesis, immune complexes and the mononuclear phagocytic system.

Immune thrombocytopenic purpura (ITP) In children this disease tends to be acute and self-limiting, conventionally managed by expectant observation or if more severe by corticosteroids. High-dose ISG, $0.4 \text{ g kg}^{-1} \text{ day}^{-1}$ for 5 days has proved as efficacious as prednisone. The disease tends to be chronic and relapsing in adults. Again, the thrombocytopenia can be corrected with similar doses of ISG, although regular maintenance doses at weekly to monthly intervals are often required. ISG therapy is useful for preparing a patient for splenectomy, but its role in long-term management remains less convincing.

The success of ISG in ITP has prompted its use in several other immunologically mediated thrombocytopenias. Postinfectious, alloimmune and neonatal reactions have responded to therapy. Occasionally, the latter have been prevented by maternal infusion late in pregnancy, although this approach cannot be relied on, irrespective of the effect on the maternal platelet count.

Other diseases Intravenous ISG is standard therapy in Kawasaki's disease, has been trialled in autoimmune neutropenia and hemolytic anemia with varying success and has been successfully used to downregulate the production of factor VIII-specific antibodies in individuals with hemophilia A. Its applications are now being extended to other conditions such as myasthenia gravis, chronic relapsing polyneuropathy, recurrent pregnancy loss and bullous pemphigoid.

A number of mechanisms have been proposed for ISG in these different conditions. All may play a variable role in different circumstances, the effect varying with time and the diagnosis. Postulated mechanisms include:

- blockade of the Fc receptors on the mononuclear phagocyte system and platelets;
- downregulation of autoantibody production by anti-idiotypic antibodies present in ISG;
- removal of exogenous antigen that initiated the disease; and
- interference with the pathogenic role of antibody, immune complexes or both.

Plasmapheresis and staphylococcal protein A column treatment of plasma These two modalities have been used to remove putative blocking factors that inhibit an otherwise effective cellular immune system from dealing with malignant disease. In fact, the evidence for the existence of such factors is wanting in human neoplastic disease. Consequently, it is hardly surprising that plasmapheresis has no immunopotentiating role in malignant disease.

Removal of 'blocking antibodies' on protein A-coated columns has shown quite impressive results in some animal models, but these successes have not been transferable to the clinic.

Adoptive nonspecific immunopotentialiation

Most nonspecific immunopotentiating maneuvers have proved disappointing in the control of human neoplastic disease. With some exceptions, this also includes the *in vitro* expansion of autologous lymphocytes from cancer-bearing patients with IL-2 and their adoptive transfer back into the patient, usually with *in vivo* IL-2 as a way of further potentiating their activation and proliferation. This method was pioneered by Rosenberg and colleagues at the National Institutes of Health (NIH) in the 1980s. The protocols used are quite complex, with patients being infused with IL-2, rested, leukapheresed, and their cells returned to them over several days after *in vitro* expansion. The toxicity is considerable, due largely to a capillary leak syndrome induced by IL-2 and results in marked fluid retention, cardiac and renal failure, respiratory insufficiency, hypotension, and an increased rate of infections. Up to 4% of patients in these studies died due to these toxic effects. Immunosuppressive therapy can reduce this, although the latter then appears to interfere with the therapeutic effect of the procedure. Some workers have claimed that infusions of IL-2 alone are just as useful.

The nature of the cells involved as LAK is uncertain. The cells exhibit potent non-major histocompatibility complex (MHC)-restricted cytotoxicity against a wide range of targets including NK cell-resistant tumor lines. Normal parenchymal cells of the same type as the tumors tend to be resistant to LAK activity. A heterogeneous population of cytotoxic cells has been found, including an NK CD3⁻ cell,

which is probably the major cell phenotype, and also a CD3⁺ cell which in culture loses its MHC restriction and kills promiscuously.

Despite the attraction of LAK therapy, which is based on sound theoretical grounds, it remains disappointing. Results in other hands have not been as effective as those obtained originally at the NIH and the modest overall rate of complete (8%) and partial (14%) responses mainly against renal carcinoma and melanoma has to be balanced against the expense involved and the complication rate. More needs to be known about the duration of remissions, for if they are not sustained then the procedure represents an enormous potential diversion of health resources for limited overall ends.

IMMUNOSUPPRESSION

Jean F Borel, Transplantation Research, Novartis Pharma Inc., Basel, Switzerland

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Regulation of the immune response can be influenced in two ways. The enhancement of the immune response is called *immunopotential* and its down-regulation *immunosuppression*. The early history of medical immunology is dominated by deliberate attempts to induce resistance to infectious agents by means of eliciting an immune response and by enhancing the immunological defense mechanisms. Vaccination or immunization with an antigen preparation can specifically protect the body against microorganisms such as smallpox, rabies or poliomyelitis. More recently, increasing awareness that several pathological conditions are caused by undesirable reactions of the immune system has led to attempts to reduce the immune response. Thus, immunosuppression is needed in transplantation to prevent the rejection of a transplanted and histoincompatible but life-saving organ as well as to induce remission and to prevent relapse in autoimmune diseases.

The advent, around 1900, of the feasibility of anastomosing vessels opened to the surgeons a wide vista into the field of transplantation surgery. The transplantation of organs such as kidneys was experimentally performed at that time by pioneers such as A. Carel in France and E. Ullman in Austria, but all attempts met with failure due to the invincible rejection phenomenon. It was Medawar who, in 1944, described the immunological basis for rejection of foreign tissues. Soon after, cell-mediated immunity and immunological tolerance were discovered by Billingham, Brent and Medawar. The investigation of the human leukocyte antigen (HLA) system since 1958, initially by Dausset and coworkers, has made a major contribution to improving organ transplantation. Finally, in the late 1950s, it was further realized that immunosuppressive methods were useful in controlling rejection.

If the immune response, as originally conceived, was to defend the individual against any foreign antigen, it should remain fully tolerant to self components. However, for various reasons, a breakdown in tolerance can occur and lead to more or less specific immune attacks directed against defined cells or organs of the host, thus inducing an autoimmune disease. The use of immunosuppressive agents has proven of therapeutic value in many such diseases, e.g. uveitis, myasthenia gravis, juvenile diabetes, psoriasis, primary biliary cirrhosis, ulcerative colitis,

systemic lupus erythematosus, nephrotic syndrome and rheumatoid arthritis.

The goal of selective immunosuppression

If any foreign material (antigen) makes its way into the body – virus, bacteria, fungi or parasites – a swift and complex immune response for destroying it is set into motion. The allelic products of the major histocompatibility complex (MHC) characterize the immunological identity of each individual. With the exception of identical twins, it is extremely unlikely that two individuals match exactly. Nature did not intend for organs to be transplanted from one individual to another. The speed and severity of rejection of a transplanted (foreign) organ is partly linked to the degree of incompatibility of MHC (HLA) antigens between donor and recipient.

Whether the antigenic trigger is a foreign microorganism, a histoincompatible transplant, or a self component to which self tolerance has been broken, the same humoral or cell-mediated immune response is set in motion. Besides the antigen-presenting cell, three main classes of lymphocytes exist to initiate (helper T cells), effect (cytotoxic T cells and antibody-producing B cells), and shut off (suppressor T cells) the immune response. In addition, natural killer cells recognize cell surface antigens in a non-MHC restricted fashion. Antibodies and killer or cytotoxic T cells are mobilized to destroy all target cells bearing the offending antigen. In the case of infection this would be a microorganism, but in the case of a transplant it is the vital life-saving organ which becomes the target of the immunological attack. In the case of *autoimmunity* it will be the cells or organs bearing the self antigen which has escaped self tolerance.

The goal of selective immunosuppression is to maintain the body's defense mechanism against viruses, bacteria, fungi, and parasites, to preserve its capacity to phagocytose necrotic cells and other debris, and finally to protect the mechanism of *immune surveillance* which eliminates malignant cells. This is outlined in **Figure 1**. On the other hand, one would like to induce antigen-specific tolerance for the transplanted organ such as kidney, liver and heart. In the case of autoimmune diseases, one would like to selectively inhibit the autoaggressive response against, for example, the retina in uveitis, the colon

Figure 1 Goals of selective immunosuppression: 1) to maintain defense mechanism against foreign (viruses, bacteria, fungi, parasites) and internal (necrotic and tumor cells) invaders (white arrows); 2) to selectively suppress host reaction against its organ grafts (black arrows), i.e. in transplantation (kidney, heart, liver); and 3) to selectively suppress the pathological immune attack directed against self target organs (retina in uveitis, islet cells in diabetes, joints in rheumatoid arthritis, etc.), i.e. in autoimmune diseases (stippled arrows).

in Crohn's disease or the joints in rheumatoid arthritis.

Although a vast range of different compounds have been reported to be capable of depressing the immune response, it has been particularly disappointing that so few of these have shown potential as immunosuppressive agents in humans. The action of many has been to suppress lymphocyte functions *in vitro* but, of those that were capable of prolonging allograft survival or of suppressing autoimmune symptoms in animals, very few have been found to be safe and effective in humans. Therefore, for a drug to be of practical use in suppressing immunological responses, it should fulfill a number of basic requirements. These are tentatively summarized as follows:

1. Its major pharmacological impact should result in the depression or suppression of the immune response in relevant *in vitro* tests as well as in several animal models.
2. The drug should be able to prevent the onset of an immune response and also be effective against immune processes once they have already developed.
3. Its mechanism of action should selectively induce *clonal deletion* or inactivation of immunocompetent cells or preferably only certain subsets and inhibit some of their functions (anergy).
4. There should be a biologically meaningful therapeutic index, i.e. safety margin between the therapeutic and the toxic dose. This index has to be determined in several species.
5. The treatment protocol should not endanger the innate and already acquired immunity against opportunistic infections.
6. Thus, the drug should only be administered at full dose for a limited period. After this critical phase, dose reduction and eventually discontinuation of the drug should become feasible.
7. The ideal immunosuppressant should, therefore, help to induce tolerance, especially in transplantation. In other words, it should allow the immune system to adapt to the foreign antigens of the transplant by progressively recognizing them as part of self. (However, the induction of tolerance in man has not yet been fulfilled.)

Development of immunosuppressive therapy

With the advent of organ transplantation, immunosuppression became a pressing problem. Most of the surgical problems of organ allografting had been solved long before it was understood how to protect the transplant from its inevitable rejection. Donor-specific or unspecific blood transfusions before transplantation and tissue matching (HLA) have clearly been shown to be of importance in prolonging graft survival; however, these measures were of value only if integrated into a chemotherapeutic protocol.

The first stage in the development of immunosuppression introduced in the late 1950s and early 1960s consisted of using cytostatic drugs and antimetabolites which were used to control the proliferation of neoplastic cells. It seemed logical to observe their effect on the equally proliferative processes of the immune response. Those cytostatic or cytotoxic agents which proved of some value were alkylating agents such as cyclophosphamide, purine analogs (thiopurines) such as 6-mercaptopurine and azathioprine, folate analogs (antimetabolites) such as methotrexate (or amethopterin), and pyrimidine analogs such as cytosine arabinoside. It can be concluded that the concept of interference at various stages of the immune response, e.g. repression of the formation of precursor cells, destruction or blockade of immunocompetent cells, suppression of proliferation and differentiation of lymphocytes and monocytes by inhibition of the biosynthesis of nucleic acids and proteins, was basically correct. However, the use of nonspecific drugs – that is drugs whose action was not limited to the immunocompetent cells – remained hazardous. This was because they acted by indiscriminately blocking or damaging all cells that happened to be in mitosis, in particular normally functioning cells that are important to the organism's survival (e.g. hematopoiesis). The major drawback to the use of these cytostatic drugs is the high risk of overwhelming infections by organisms, many of which are not normally pathogenic (opportunistic infections). Although graft rejection could be held at bay by the use of these compounds, which interfered nonselectively with the induction or expression of the immune response, the toxic side-effects were usually so severe that the overall results were not considered satisfactory.

The next step was, therefore, the development of lymphocytotoxic drugs or procedures which were mostly restricted to the elimination of the immunocompetent cells, mainly the lymphocytes. This goal could be achieved by the use of very heterogeneous means, such as total lymphoid irradiation, thoracic

duct drainage, splenectomy, thymectomy, anti-lymphocyte serum or globulin, and steroids. Corticosteroids are naturally occurring hormones secreted by the adrenal cortex, of which cortisol (hydrocortisone) is by far the most powerful component known to possess lymphocytolytic activity, particularly with respect to T lymphocytes, to inhibit lymphokine production, and to exert a stabilizing effect on the lysosomal membranes, along with those of other cellular organelles. These effects are dose- or concentration-dependent. Corticosteroids not only intervene at many points of the immune response, such as preventing lymphocyte recirculation and generation of antibody-producing and cytotoxic effector cells, but they also possess a remarkable anti-inflammatory potency. They inhibit neutrophil adherence to the vascular endothelium at an inflammatory site and suppress monocytic functions such as microbicidal activity, monocyte response to lymphokines, and release of monokines. Antilymphocyte serum (ALS) or antithymocyte globulin (ATG) is prepared by the injection of lymphocytes or thymocytes into a xenogeneic species. Human thoracic duct cells or thymocytes can be used as antigens to immunize rabbits and horses; the purified immunoglobulin fraction containing the relevant antithymocyte antibodies is then used in the clinic for intravenous injection. Since regular administration of ATG leads to sensitization against xenogeneic proteins (antibody production directed against the antihuman ATG from the immunized species), this type of adjunctive treatment is usually given short term to overcome a graft rejection crisis or early to prevent sensitization to the allograft.

Immunosuppressive therapy during the 1960s and 1970s consisted of combinations of different agents intended to produce maximal suppression while keeping the side-effects as few as possible. The most common immunosuppressive protocol was the combination of azathioprine and corticosteroids, which significantly improved allograft survival but also created a variety of severe side-effects, especially long term, among which were overwhelming, sometimes fatal infections, direct organ toxicities, slow wound healing, anemia, leukopenia, diabetes, osteoporosis, stunted growth in children, and even malignancies. The average 1 year kidney survival rate from all transplantation centers reached about 50% using this protocol while in outstanding centers the figures reached 80% and higher. Under those conditions, liver transplantation remained an experimental procedure and heart transplantation, which had enjoyed a transient burst of activity in the late 1960s, was abandoned in all but three centers worldwide. In autoimmune diseases, steroids were most commonly

used, usually in increasing doses with time, and severe cases were sometimes treated with azathioprine, cyclophosphamide or methotrexate.

The current or third phase of immunosuppressive therapy is that of immunopharmacology, which is characterized by selective regulation of defined subpopulations of immunocompetent cells. This stage deals with new pathways and is aimed at the development of agents or procedures with selective action on the acquisition of immunologic responsiveness, recognition of immunogenic stimuli by receptor-bearing cells, induction of differentiation and maturation of lymphocytes, cellular interactions, and modulation of effector functions. Cyclosporin (WHO)/cyclosporine (US Adopted Name Council)/cyclosporin (British Approved Name) emerged as the first drug that fulfilled these requirements to some extent and which has proved of permanent clinical value. However, other promising and original attempts need to be mentioned here, such as the new technology of monoclonal antibodies directed toward lymphocyte subsets and their products, and other cytokines as well.

The final stage of immunosuppression will be the induction of antigen-specific depression of allograft reactivity. Classical transplantation tolerance has been induced in a developing immune system, but it is very difficult to achieve in a fully developed immune system. Several experimental approaches have been more or less successfully used in various models, but their practicability for clinical purposes appears still to be unproven.

Retrospectively, the 1980s can be viewed as the cyclosporine era. Although this novel immunosuppressant has triggered important developments in transplantation, autoimmunity and basic immunology, it is by no means the only factor responsible for the numerous advances recently achieved in these fields. Despite the astounding progress of experimental immunology in gaining more insight into the mechanisms controlling an immune response and, therefrom, in learning how to bypass an undesirable immune reaction, it still appears that clinical immunosuppression will continue to rely for this decade on a chemotherapeutic strategy using a subtle combination of more selective as well as better tolerated immunopharmacologically effective drugs. If not yet evident, a revolution is always possible.

Modern trends in immunosuppression

The 1990s have seen the emergence of several new drugs that exhibit marked immunosuppressive activity in clinical trials: tacrolimus (FK506), sirolimus (rapamycin), mizoribine and spergualin. Like

cyclosporine (cyclosporin A), they are all natural products originally isolated from cultures of microorganisms. Cyclosporine, a lipophilic, cyclic peptide, and tacrolimus, a lipophilic, macrocyclic lactone, have very similar mechanisms of action. They both act specifically on lymphocytes by inhibiting gene transcription induced by calcium-dependent pathways, i.e. they block the progression from G_0 to G_1 of the cell cycle. Sirolimus is a macrolide which inhibits the growth factor-dependent pathway of T cell proliferation by blocking the progression from late G_1 to the S phase. Sirolimus acts synergistically with cyclosporine, but not with tacrolimus, in the suppression of T and B cells. The antibiotic mizoribine, a nucleoside analog that inhibits guanosine (GMP) synthesis, and gusperimus (15-deoxyspergualin), a derivative of spergualin that suppresses polyamine biosynthesis, exhibit immunosuppressive activity without lymphocyte selectivity. Mizoribine, in contrast to gusperimus, has also been claimed to induce at least additive effects when used in combination with cyclosporine. Gusperimus has proved particularly effective in suppressing experimental xenograft rejection.

Moreover, mycophenolate mofetil (RS61443), a mycophenolic acid derivative that interferes with *de novo* purine synthesis, has yielded encouraging clinical results when used in combination with cyclosporine. In clinically attainable concentrations both sirolimus and mycophenolic mofetil are known to inhibit smooth muscle cell proliferation in the neointima, a major pathogenic mechanism that causes chronic rejection. In an appropriate combination with cyclosporine they might, therefore, help control chronic rejection in transplanted patients – currently the principal limitation of long-term graft survival.

While significant progress has been made with chemical immunosuppressants, other approaches have concentrated on using immunomodulating biological agents. Polyclonal antibodies present in anti-lymphocyte serum have been replaced with monoclonal antibodies (mAbs) that target selected cell surface antigens. OKT3, a T cell-depleting CD3-specific mAb, is the first mAb to have been introduced successfully in the clinic. Monoclonal antibodies directed against T helper cells (anti-CD4) and the interleukin 2 receptor (anti-CD25) have shown promising results in clinical trials. Another approach is to delete specific cell populations by using immunotoxins. These molecules consist of two fused parts, one being a recognition moiety and the other a toxic moiety (e.g. ricin or diphtheria toxin). In addition to T and B lymphocytes, antigen-presenting and regulatory cells also express characteristic target determinants. For instance, selected peptides have

been synthesized that bind to MHC antigens and thereby compete with antigen presentation.

A further option is to block costimulatory molecules, in particular CD28 and CD40, a strategy that leads to anergy due to loss of second signal activation. Since cytokines play a critical role in the process of an immune reaction, attempts have been made to neutralize them with soluble receptors, as an alternative to anticytokine mAb. Interference with adhesion molecules (selectins, integrins) on activated graft-invading leukocytes and on graft endothelial cells is a further means of intervening to prevent allograft rejection. Treatment with recombinant cytokines may also result in immune deviation. Finally, it is known that the modification of the graft by culture procedures or ultraviolet irradiation can induce prolonged survival, presumably by the removal of the passenger leukocytes (antigen-presenting cells) which play an important role in allograft rejection.

Although many of these widely differing approaches toward selective suppression or modulation of the immune response have yielded reasonably encouraging results under experimental conditions, they are not yet generally applicable to clinical practice. However, several of these procedures are now cautiously being tested in patients receiving organ transplants or suffering from autoimmune diseases. The appropriate combination of some of these chemical drugs and biological agents integrated into a well-synchronized regimen may eventually achieve graft tolerance – at least func-

tional unresponsiveness – or long-term remission in autoimmunity.

IMMUNOTHERAPY OF ALLERGIC DISEASES

Kent T HayGlass, Department of Immunology, University of Manitoba, Winnipeg, Canada

Allergen immunotherapy represents the dominant immunologic, as opposed to environmental or pharmacologic, approach to management of allergic diseases such as allergic rhinitis, conjunctivitis and asthma. It was developed empirically, coincident with the modern-day discovery of allergy by Portier, Richet and von Pirquet. In essence, it involves identification of the allergen(s) to which a patient exhibits immunoglobulin E (IgE)-dependent sensitivity followed by subcutaneous administration of minute amounts of natural extracts containing these allergens. The goal is lasting modification of immune processes responsible for the maintenance of atopic symptoms. Other, infrequently used, forms of desensitization (i.e. IgE-mediated drug reactions)

operate by different mechanisms and are not reviewed here.

History

Given its beginnings at the turn of the century, the theory underlying allergen desensitization was closely associated with that of vaccination. Allergens, common environmental antigens that provoke allergic responses in some individuals, were seen as conceptually similar to bacterial toxins. It was thought that individuals with undesirable (hypersensitivity) responses to such substances would develop a protective immune response upon exposure to increased doses of allergen, resulting in

a qualitative shift from immediate hypersensitivity to clinical tolerance. Beginning in 1909–11, Noon and others established immunization programs for 'desensitization' that have continued largely unchanged to the present.

The question of efficacy

In insect venom immunotherapy, protection is achieved in well over 90% of subjects following a short (usually several day) course of injections. Efficacy is commonly tested by deliberate administration of an insect sting challenge in the presence of a physician, yielding clear-cut evidence of success or failure. In contrast, the efficacy of immunotherapy for inhalant allergens, used in therapy of allergic rhinitis or allergic asthma, remains controversial. Proponents argue that allergen immunotherapy is highly effective and that the equivocal results are attributable to use of insufficient or poorly prepared allergen extracts, use of inappropriate or insufficiently rigorous criteria for patient selection or unwillingness of patients to complete a sufficiently long course of treatment. They draw support from statistically significant differences that have been observed in a number of parameters measured in randomized, double-blind, placebo-controlled studies. On this basis, the formal position of medical associations in most developed nations is that desensitization with standardized allergenic material in high doses is effective in patients with an allergy to insect stings, allergic rhinitis, conjunctivitis and, in some cases, allergic asthma when patients have been selected based on meticulous history corroborated by positive results of skin tests and for whom avoidance of allergens and drug therapy is not sufficiently effective. The problem is that the degree of success achieved is highly variable and unpredictable on an individual basis. Generally, patients with multiple unrelated sensitivities have more severe or complex disease and do less well. Consequently, enthusiasm for allergen immunotherapy varies widely between different countries and groups of physicians. In most instances, the technique requires several months to years of therapy, hence substantial time and financial commitment with an uncertain probability of success and a very low, but real, risk of anaphylaxis resulting from treatment.

Current practice

Immunotherapy is easy to administer and in most patients is well tolerated, but to attain substantive efficacy strict criteria for patient selection are necessary. A variety of factors must be taken into account

but the first is to establish that the clinically apparent sensitivity is IgE-mediated. As no single objective test provides sufficient information, IgE-mediated disease is generally diagnosed by correlating history, skin tests and often specific IgE levels. Once the clinically relevant antigens have been identified, a course of treatment involving a series of subcutaneous allergen injections is begun. As most patients are polysensitized, this can require coadministration of multiple allergens. Initial injections contain very low amounts of allergen to minimize the intensity of local reactions and risk of systemic anaphylaxis. On each subsequent visit the amount of allergen, which may be aqueous or bound to adjuvants such as aluminum salts, is increased until a maintenance dose, often close to the maximum amount of antigen tolerated, is reached. The patient is then kept under medical supervision for 20–30 min in case of anaphylaxis or acute exacerbation of asthmatic symptoms. Contraindications include diseases of the immune system, conditions complicating management of adverse reactions to immunotherapy (i.e. coronary heart disease, hypertension or treatment with β -adrenergic antagonists, sometimes pregnancy) and patients developing severe reactions during therapy.

Allergic patients commonly vary by more than a thousand-fold range in their degree of allergic sensitivity. It is for this reason that the cumulative dose used in allergic immunotherapy is related to what can be tolerated by the patient. Doses that are too low are safe but have little or no effect relative to placebo. Doses that are too high may be effective but carry an increased risk of systemic reactions. Given the wide variability in the subject population and, until recently, poor standardization of the amount of biologically active allergen present in nominally identical commercial preparations, safe and effective desensitization is generally considered to require specialty training in allergology.

In contrast to other forms of desensitization therapy for common inhalant allergens (dust mite, cat, tree and grass pollens), which typically require 2 to many years of treatment, venom immunotherapy is commonly initiated via 'rush' methods in which rapidly increasing amounts of venom are injected over a period of several days. Regular booster treatments are usually required although recent studies have begun to address how long protection persists in the absence of continued therapy.

In the mid-1980s a cluster of immunotherapy-related fatalities in the UK and studies indicating that desensitization programs in the US had resulted in an average of approximately one fatality a year over 42 years resulted in an IUIS/WHO sponsored re-examination of desensitization practices. Serious

problems were primarily found to occur when therapy was administered by physicians inexperienced in its use and when standardized procedures for recognition and control of systemic reactions were not in place. A series of guidelines were developed that have been widely adopted.

Mechanisms of action

While immunotherapy is generally considered the final medical modality (after allergen avoidance or pharmacologic control of symptoms), and usually requires several years to make its effects seen, its appeal springs from a desire to modify the underlying disease state that is responsible for hypersensitivity. As such it has stimulated much interest by basic and clinical immunologists attempting to identify the mechanism by which it operates. No consensus is currently possible. Our inability to definitively identify a causative relationship linking changes in objectively measurable parameters (previously induction of 'blocking' IgG, currently inhibition or redirection of T_H2 -like cytokine responses to allergen) and clinical improvement continues to be the greatest hindrance impeding efforts to give immunotherapy the success rate of, for instance, immunization programs for tetanus or polio. Based on the status of desensitization following a century of empiricism, substantial progress will be difficult until a mechanistic cause-and-effect relationship is established.

Future developments

A major factor that has impeded accurate clinical diagnosis of allergy, development of immunotherapeutic protocols and basic research in hypersensitivity diseases has been the highly variable, poorly standardized quality of commercial allergen preparations available to clinicians and researchers for most of this century. Until recent years, most were characterized based on the total protein content rather than the amount of specific allergen present. International standardization based on units of biological activity rather than mass has partially dealt with this concern but such materials remain highly heterogeneous. The identification, cloning and expression of recombinant allergens over the last decade is having substantial impact on research, diagnosis and, perhaps in the future, therapy of allergic diseases.

Antigen-specific methods

A number of strategies that may result in substantial improvements in safety and efficacy are on the ho-

rizon (Table 1). Use of ultrapure (recombinant) allergens in classical immunotherapy protocols offers homogeneity, reproducibility and perhaps improved efficacy compared to the complex mixtures that currently dominate clinical practice. Several approaches (i.e. chemical modification of allergens, DNA vaccines) have been proposed that aim to reorient ongoing cytokine response *in vivo* from those of T_H2 -associated bias to T_H1 -dominated patterns. Alternatively, by identifying the immunodominant peptides driving allergen-specific T cell reactivity in humans, it may be possible to functionally delete them from the periphery upon inhalation, injection or oral administration. Each of these strategies focuses on altering the activity of allergen-specific regulatory populations (largely but not exclusively CD4 T cells) responsible for maintaining the allergic state.

A consistent finding from animal and human studies is that abrogating or redirecting established (memory) responses *in vivo* is much more difficult than directing the initial induction of naive cells to a desired response. Consequently, there has been discussion of the potential utility of prophylactic desensitization of children with a high (genetic) probability of developing asthma to common environmental allergens.

Antigen-nonspecific approaches

An independent series of strategies that may prove useful do not seek antigen specificity, circumventing a need for detailed identification of the specific allergens to which any particular patient is sensitive. Collectively, they differ from strategies seeking to inhibit or redirect T cell activation and antibody responses to semipermanent changes in clinical responsiveness

Table 1 Recent developments with potential for desensitization strategies

Use of recombinant allergens in classical desensitization protocols
Identification of immunodominant T cell epitopes and induction of T cell anergy with allergen-derived peptides
Redirection of established allergic responses to T_H1 -dominated patterns using modified native or recombinant allergens
DNA vaccines
Oral or intranasal induction of tolerance with intact antigens or immunodominant peptides
Antagonizing the action of T_H2 -associated cytokines via administration of mutant cytokine (i.e. IL-4) molecules or antibodies specific to cytokine receptors
Local administration of exogenous cytokines (i.e. IFN γ , IL-12)
Anti-IgE-based approaches

in that they assume a requirement for chronic treatment much as do current pharmacologic methods of symptomatic control. Candidates include: 1) rIL-4 engineered to bind but not trigger the IL-4 receptor, 2) antibodies specific to cytokines or cytokine receptors that aim to block the production or function of the IL-4 necessary to sustain ongoing IgE responses *in vivo* and 3) antibodies that bind ϵ -specific determinants on free but not mast cell/basophil-bound IgE molecules, thereby impeding their interaction with high-affinity IgE receptors without triggering already bound IgE. Substantial progress has been made in genetically engineering these antibodies to reduce their inherent immunogenicity in humans.

Each of these approaches has shown promise in preliminary animal studies and is at some stage of clinical trials. Each also faces substantial hurdles before it can be considered as a major improvement capable of raising the efficacy of desensitization programs. Detailed discussion of novel approaches is accessible via the citations listed under Further reading.

Summary

From strictly empirical beginnings, immunologists and clinical practitioners have developed immunization strategies that efficiently protect large populations from a host of infectious diseases. Increased understanding of how protective immune responses are initiated and maintained has played a substantial role. With allergic diseases currently affecting 20–25% of the population in developed nations at substantial social and financial cost, the need for consistently effective strategies is readily apparent. Better understanding of 1) the means by which exposure to ubiquitous environmental antigens leads to allergic sensitization versus clinical tolerance, 2) immunologic mechanisms responsible for maintenance of

hypersensitivity diseases and 3) the cause-and-effect relationship underlying successful immunotherapeutic regimens are key priorities in moving desensitization programs to high levels of efficacy and acceptance.

IMMUNOTHERAPY OF AUTOIMMUNE DISEASES

Marc Feldmann and Ravinder N Maini, Kennedy Institute of Rheumatology, London, UK

The term 'immunotherapy' is used in two somewhat different senses. One is 'therapy of the immune system', aimed at targets ranging from antigen-presenting cells to activated T cells, macrophages and B cells. Another context is the use of immunological reagents, such as antibodies, T cells or their modifi-

cations in therapy. Immunotherapy in both senses has been applied vigorously in animal models of autoimmune diseases, and increasingly attempts are being made to apply immunotherapy to a wide range of human diseases.

Types of immunotherapy

A major goal of immunotherapy is to selectively reduce the unwanted immune response, but retain other protective immune responses. Existing anti-immune drugs are not clearly selective. Selectivity could be obtained in a variety of ways. One is by the induction of immunological tolerance. This comes in various forms, all defined as antigen-induced, antigen-specific immune suppression. Other approaches, less specific, would include inhibiting a portion of the HLA class I and II antigens or the HLA-peptide complex involved in presenting peptides to T cells. Alternatively, as some T cell responses to antigen use a narrow range of T cell receptors for antigen, targeting a subset of T cell receptors (TCRs) by using monoclonal antibodies or superantigens is being attempted. Targeting lymphocytes bearing markers of activation, such as interleukin 2 receptor (IL-2R, CD25), also offers a degree of selectivity.

At the other end of the spectrum are drugs which are not selective, inhibiting all lymphocytes following activation (e.g. cyclosporine) or all lymphocytes responding to cytokines such as IL-2 (e.g. rapamycin).

Selective immunosuppression

Tolerance in its classical definition depends on knowing the antigenic epitopes to be recognized, and hence a major drawback of studies in human and experimental autoimmunity is our lack of understanding of the important epitopes. Nevertheless there are a variety of experimental approaches which are finding their way into human application, at least to the clinical trial stage. A major objective is to ensure that in established disease, with an ongoing immune response, the therapeutic strategy does not potentiate rather than suppress the immune response.

Oral tolerance

Oral tolerance has been described for many years, first by Merrill Chase in guinea pigs. Most recently it has been popularized by H. Wiener and colleagues, and clinical trials of bovine collagen type II in rheumatoid arthritis and myelin basic protein in multiple sclerosis are in progress, run by Autoimmune Inc. Multiple mechanisms of oral tolerance have been proposed, from inducing apoptosis at high doses to inducing regulatory T cells at low doses. An improved variant may be inhalation tolerance, via the nose, which is more potent, and has been popularized by David Wraith.

Peptide-induced tolerance

Peptides given systematically, without adjuvant, are of low immunogenicity and are being developed for therapy. Trials of myelin basic protein (MBP) peptides, based on the 89–102 immunodominant region, are in progress, with different variants being run by Neurocrine Inc. and Immunologic. Neurocrine's trial involves using peptide derivatives known as 'altered peptide ligands', which upon binding to TCR do not elicit a complete immune response, but instead favor induction of tolerance.

Peptide-MHC complexes

Peptides elicit their effects after binding to the major histocompatibility complex (MHC) class I or II binding groove. It was thus proposed that it may be more effective to induce tolerance by treatment with pre-formed MHC class II-peptide complexes. This is effective in animal models, and a clinical trial of an HLA-DR2-MBP peptide complex is being initiated by Anergis Inc.

In the past, it was considered that saturating MHC peptide-binding grooves with nonimmunogenic peptides may be an effective strategy, but this was found not to be the case. Nonpeptide MHC blockers are in development (Zeneca). There are also clinical trials using immunization with MHC-derived peptides, which are designed to induce anti-MHC autoantibody, for example to the DR4/DR1 conserved 'shared' epitope involved in rheumatoid arthritis (Anergis Inc.).

TCR peptides

Peptides from the TCR have been shown to induce a protective immune response in experimental allergic encephalomyelitis (EAE), and such an approach is being attempted in humans in phase I studies (Immune Response Inc.).

Bystander suppression

It was initially thought that a major problem of all the tolerance regimes designed to inhibit the dominant autoimmune response would be the fact that they would block only a fraction of the autoimmune responses, and with time, weaker residual responses would amplify to restore the pathologic status quo. However, there is increasing evidence that this may not be the case, and that 'bystander suppression' may develop.

The phenomenon of bystander suppression is that during 'tolerization' with a major epitope, responses to other epitopes found in the same site, either on the same or other proteins, are also diminished. This

has been reported to occur with oral tolerance, inhalation tolerance, and also with injected peptides. The mechanism is not well understood, hypotheses range from the production of protective T_H2 cells producing immunosuppressive cytokines such as IL-4 or IL-10, or ' T_H3 ' cells producing immunosuppressive cytokines such as transforming growth factor β (TGF β).

Nonspecific immune suppression

Even 'nonspecific' immune suppression comes in degrees of specificity. One popular target is activated T cells. It could be predicted that activated T cells would be enriched for cells involved in the autoimmune process. However this prediction may not be useful, as there is evidence that many activated T cells are involved in the endogenous immunoregulation which diminishes the immune responses to auto and other antigens.

Activation antigens that have been used as the target for immune suppression include CD25, the activatable component of the high-affinity IL-2 receptor. IL-2 toxin has been used by Seragen. Antibodies to CD25 by Sandoz and Hoffman La Roche appear to be effective. OX40 is another activation antigen which is being considered as a therapeutic target. Immunosuppressive drugs like cyclosporine and FK506 are widely used in transplantation and cyclosporine is being increasingly used in rheumatoid arthritis (in combination with other drugs) and in psoriasis. In autoimmunity, glucocorticoids and methotrexate, which are both immunosuppressive and anti-inflammatory are widely used (e.g. in systemic lupus erythematosus and rheumatoid arthritis).

Antibody-dependent immunotherapy

The capacity to use antibodies for immunotherapy has been reported by a number of groups, and provides a very flexible and specific approach. This approach has been used in a wide spectrum of diseases, in transplantation and cancer, as well as autoimmunity. One of the virtues of antibody-mediated therapy is its molecular specificity, which, unlike the case with organic chemical drugs, is precisely known. Thus, cross-reactions can be readily monitored and therapeutic trials offer insight into pathophysiology.

The murine monoclonal antibody OKT3 developed by Patrick Kung was the first antibody to reach the market for transplant rejection episodes, and is still in use. Because murine antibodies are highly immunogenic in humans, repeated administration was not likely to be practical in the treatment of chronic disease, unless the effect was permanent.

Subsequent developments have altered the structure of murine antibodies so that they more closely resemble human antibodies in order to reduce immunogenicity. Replacement of the Fc and hinge regions leads to 'chimeric' antibodies, retaining the murine Fv, and more recently only the murine hypervariable regions have been 'grafted' on to a human Ig backbone, forming 'humanized' antibodies. With the generation of transgenic mice with a considerable part of the functional human Ig gene locus in place, the goal of developing fully human antibodies is also close to becoming realized. Phage display technology has been used to construct recombinations of human heavy and light chains. These immunoglobulins can be selected to bind molecular targets, and can be used for antibody. Whether these strategies will prevent immune responses to neopeptides in the idiotypic (hypervariable) region is unclear.

One of the most studied antibodies is anti-CD4. It has been shown by H. Waldmann in animal models that this promotes the development of immunological tolerance. The mechanism of this is not fully understood, and probably several mechanisms exist. Both lytic (depleting) and nondepleting antibodies can be protolerogenic, the latter more so. The mechanism of tolerance involves the generation of regulatory T cells and takes several weeks to reach optimal effects. Since such tolerance is capable of being transferred by T cells, the induced tolerance is 'infectious'. In humans anti-CD4 has been used extensively. Initial trials with lytic anti-CD4 in rheumatoid arthritis were not effective, but current trials of nonlytic anti-CD performed by SmithKline Beecham and Glaxo-Wellcome are more encouraging, reflecting the animal model experience.

Immunotherapy with anti-CD7 and with anti-CD5 (the latter conjugated to ricin) have not been effective in rheumatoid arthritis. CAMPATH-1H reacting with CD52 present on T, B and monocytic cells is a very lytic antibody, and may be effective in rheumatoid arthritis, although its apparent toxicity has prevented its use in randomized placebo-controlled trials. Nevertheless, it has had dramatic success in vasculitis and in lymphomas and some success in multiple sclerosis.

Antibodies to cytokines have been used for immunotherapy. The most widely studied is anti-tumor necrosis factor α (TNF α), which was initially used in sepsis, without clearcut success. Subsequent open and placebo-controlled clinical trials in rheumatoid arthritis and Crohn's disease have been highly successful and reproducible using two different antibodies, first with cA2 from Centocor Inc. and subsequently CDP571 from Celltech. In addition, two immunoglobulin (Ig) Fc-TNF receptor fusion pro-

teins produced by Immunex (p75) and Roche (p53) have both been shown to be effective.

Antibodies to IL-6 and IL-6R have been reported to be beneficial in very small open studies in rheumatoid arthritis.

Fusion proteins, comprising the IgG Fc region coupled to a receptor, have been used for two reasons: in order to prolong half-life in the blood and to augment avidity due to the presence of two combining sites. In addition to the above-mentioned TNFR Ig proteins, another which has entered trials is CTLA4-Ig (Bristol Myers Squibb). This protein binds to the CD80 and CD86 costimulatory ligands on antigen-presenting cells for CD28, and is very effective in animal models.

Cytokines with immunoregulatory properties have been used for immunotherapy and clinical trials. These include IL-10 for Crohn's disease and rheumatoid arthritis (Schering Plough), IL-11 for Crohn's disease (Genetics Institute) and IL-4 for rheumatoid arthritis (Schering Plough). The clinical trials are based on the effectiveness of these cytokines in relevant animal models, but of these only IL-10 in Crohn's disease has yet reached the clinical trial stage where its effectiveness has been successfully assessed.

Interleukin 1 receptor antagonist has been used in sepsis without success, but recent trials in rheumatoid arthritis by Amgen Inc. have shown a trend to some benefit, not so much in reducing inflammation, but in reducing the rate of joint destruction as assessed by serial X-rays of the hands.

Conclusions

There is currently a large endeavor to assess which immunotherapeutic successes in animal models will translate to humans. The results are encouraging, and from little new activity in therapeutic trials in the 1980s, a wide spectrum of new immunotherapeutic approaches are under development in the clinic. Whilst not all will succeed, the preliminary data on a number of approaches are sufficiently encouraging to indicate that immunotherapy will revolutionize the treatment options in autoimmunity in the next few years.

IMMUNOTHERAPY OF TUMORS

Nicholas D James, University of Birmingham, CRC Institute for Cancer Studies, Birmingham, UK

Karol Sikora, Department of Clinical Oncology, Royal Postgraduate Medical School, Hammersmith Hospital, London, UK

The concept of the immune system being involved in the development of cancer and of manipulating it as a part of cancer therapy dates back almost 100 years to the experiments of William Coley with bacterial toxins ('Coley's toxin') used in the treatment of advanced breast cancer, apparently with some success. Ehrlich developed the concept of immune surveillance against the development of cancer, the immune system acting to detect and eliminate cancerous or precancerous cells. This hypothesis has received new impetus with the recent development of monoclonal antibodies and recombinant cytokines,

particularly the interferons and more recently interleukin 2 (IL-2), thereby providing powerful tools for the manipulation of the immune response.

For immune surveillance against cancer to be plausible theory, cancer cells must express antigens recognizable as foreign by and accessible to the immune system, which must in turn be able to mount a response against cells bearing such antigens. Such a theory must also account for the somewhat bizarre tumors seen in patients with immunocompromised states such as post-transplant immunosuppression and the acquired immune deficiency syndrome

(AIDS), coupled with the failure to observe a large excess of the commoner epithelial malignancies in such disease states.

Tumor antigens

These may be examined under a variety of headings, not necessarily mutually exclusive: chemically induced antigens, virally induced antigens, major histocompatibility antigens, differentiation antigens, embryonic antigens, and inappropriate expression of adult proteins.

Chemically-induced antigens

Ideally, for an immune response to develop against a tumor, it should possess tumor-specific transplantation antigens (TSTAs). In animal models, chemically induced tumors in mice possess TSTAs of varying degrees of immunogenicity that are unique to each tumor and will be rejected by immunocompetent animals. Although many spontaneous human tumors are presumed to be chemically induced, for example lung and bladder cancer, such tumors are poorly immunogenic, suggesting the model is not of general applicability. The chemical nature of animal TSTAs remains unclear.

Virally-induced antigens

Tumors induced by viruses express antigens that are not found in uninfected cells. The tumor antigens expressed are consistent and are virally encoded. As with chemically induced tumors, the immunogenicity of the virally induced tumors varies with different models. As the virally induced antigens are the same, the difference in response must lie at the host level. Tumors induced by simian virus 40 (SV40) in mouse models are rejected by immunocompetent animals. It has been established that the response to such tumors is major histocompatibility complex (MHC)-restricted, providing a clue as to how human tumors may escape immune surveillance by downregulating MHC antigen expression. Tumors induced by SV40 have not been described in humans but another group of DNA viruses, the human papillomaviruses (HPVs), are implicated in the etiology of a variety of anogenital cancers, particularly carcinoma of the cervix. However, the HPV genes with transforming potential are the early genes E6 and E7, which probably act by binding to the antioncogenes p53 and Rb. There is currently much research examining targeting HPV oncoproteins as part of a vaccine strategy.

A slightly different pattern of findings apply to lymphomas induced by Epstein-Barr virus (EBV) in that the virus immortalizes the host cell (e.g. the B

lymphocyte) by means of early viral proteins. However, the cells do express viral antigens on their surface, allowing recognition and elimination of virus-infected cells by the immune system. In immunocompromised hosts, such elimination does not occur and the immortalized lymphocyte continues to divide and eventually may acquire further mutations resulting in malignant transformation. However, in established Burkitt's lymphoma, the only viral protein detectable is EBNA1, which may or may not be immunogenic and is the subject of current intensive investigation. It has recently been demonstrated that some immunosuppression-related lymphoproliferative disorders can be eliminated if the immunosuppression can be reversed.

The EBV/Burkitt's model fits the Ehrlich immune surveillance hypothesis in that the tumor precursors express TSTAs which can be identified by the immune system and the cells bearing the antigens eliminated before or in some cases even after a cancer develops, unless the host immune response is compromised, for example by post-transplant immunosuppression, AIDS or chronic malaria. In contrast, the HPV-induced tumors, although similar etiologically in some ways, do not appear to produce TSTAs accessible to the immune system in most cases. However, there is now evidence linking HLA types to risk of development of invasive carcinoma (see below) and thus ability to recognize viral proteins may be a factor in tumor progression. In addition, it is becoming apparent that anogenital squamous cell carcinomas, which share a likely HPV-related etiology, are increased in incidence in HIV infection and in the case of cervical carcinoma are now an AIDS-defining characteristic.

The association of Kaposi's sarcoma (KS) with sexually acquired human immunodeficiency virus (HIV) infection, and case reports of KS in HIV-negative homosexuals in San Francisco has led to the suggestion that induction of KS requires an ineffective cofactor, transmitted primarily by sexual contact and presumed to be viral. Precise figures for African patients with AIDS are more difficult to obtain but the pattern appears to be similar in that KS is relatively common and the principal mode of transmission of HIV among adults is sexual. Immunosuppression is an independent cofactor as KS also occurs among patients with other congenital or acquired immunodeficiency states such as post-transplant immunosuppression. Further KS lesions may regress in such patients if the immunosuppression is reversed. The prognosis of AIDS/KS correlates with the degree of immunosuppression of the patient.

Embryonic antigens

Carcinoembryonic antigen (CEA) is a fetal glycoprotein detectable on cells and in the serum of patients in a proportion of gastrointestinal malignancies. It has, however, proved disappointing as a tumor marker.

α -Fetoprotein, a fetal albumin, and human chorionic gonadotropin (hCG) β chain can also be detected on cells and in serum in a variety of malignancies including germ cell tumors and hepatocellular carcinoma and are useful as markers of established disease and in diagnosis. However, they are not sufficiently specific to be used for screening.

The importance of embryonic antigens lies in the light they shed on the underlying pathogenesis of the disease. The removal of controls on normally tightly regulated genes, in this case genes only expressed *in utero* (incidentally, a time of rapid growth – the human fetus grows faster than any malignant tumor), is likely to play an important role in the oncogenic process.

More recently, a series of probable embryonic antigens have been demonstrated to be present in a wide range of tumor types. These antigens have been identified using cytotoxic T lymphocytes (CTLs) to screen expression libraries derived from tumor cells. The initial family of antigens, the MAGE (melanoma antigen) family of melanoma tumor antigens have been further characterized to establish the precise peptide sequences necessary for presentation on defined HLA proteins. The MAGE proteins are of unknown function but are expressed during fetal development and in testis and brain in the adult. They are expressed in a wide range of common adult tumors in addition to melanoma. Despite their presumed fetal developmental functions, the method used to isolate the antigens, based on identification by CTLs, shows that these proteins are potential immune targets. Planning is underway to use the peptide epitopes described above in immunotherapy studies.

Inappropriate expression of proteins present in adult tissues

Cancers result from a series of mutations in normal cellular control mechanisms, resulting in either loss of inhibitory controls (so-called tumor suppressor genes) such as p53 and Rb, or gain of function mutations in positive regulators, usually involved in signal transduction pathways (so-called oncogenes). A number of these mutations lead to the expression of mutant proteins which therefore are potentially recognizable as foreign antigens. The malignant phenotype may also result in the inappropriate

expression of adult proteins, for example, ectopic ACTH production by small-cell lung carcinomas, which may be detected in biopsy specimens by immunostaining.

Major histocompatibility antigens

An effective immune response requires that a suitable target antigen exists. However, if the immune system is not presented with antigen by antigen-presenting cells, then no response will be possible. The MHC system is responsible for antigen presentation at the cell membrane and for interaction with T helper cells. Presentation of different epitopes is dependent on the MHC class I molecules present in the cell. Thus tumor antigens would be presented by some but not all HLA class I molecules and it should thus follow that either HLA type or decreased expression of HLA molecules on tumor cells may influence prognosis if escape from immune recognition is a factor in tumor progression. There is evidence from a variety of tumor types that downregulation of HLA expression occurs during disease progression. A variety of human tumors including lung, breast and skin tumors showed low levels of class I MHC expression. In contrast, benign epidermal lesions showed normal MHC expression, whereas a series of 15 basal cell carcinomas lacked both class I MHC and β_2 -microglobulin. Similar results have been obtained with squamous cell skin carcinomas. This phenomenon thus applies both to tumors that respond to immunotherapy such as melanoma as well as tumors not traditionally susceptible to immunotherapy. Bladder cancer is particularly intriguing as superficial disease can be effectively treated with intravesical BCG. Responses can be shown to be cell mediated and accompanied by markers of immune response such as release of cytokines including interleukins and tumor necrosis factor α . Muscle invasive tumors are not susceptible to BCG and have downregulated MHC expression, suggesting that this may be a factor in the development of invasive potential.

It has been known for some time that interferons modulate expression of MHC antigens, control being at the transcription level, providing one (though not the sole) rationale for their use in malignant disease. In contrast, N-myc expression induces downregulation of class I MHC in neuroblastoma cell lines and N-myc amplification is known to correlate with prognosis in neuroblastoma. Particularly intriguing in this context is the observation that patients with Evans stage 4S neuroblastoma, who have extensive disease, have a normal N-myc copy number and usually experience spontaneous tumor regression in con-

trast to the extremely poor prognosis of other patients with disseminated neuroblastoma.

It would be predicted that certain HLA types will be unable to present certain antigens and that this may allow more rapid tumor progression. There is evidence associating specific HLA types with risk of progression of cervical intraepithelial neoplasia to invasive carcinoma. As there is a well-defined role for human papillomaviruses in the etiology of this disease (see above), the possibility of targeting viral antigens for therapy is attractive and the converse, that the concept that the inability to 'see' viral antigens may be etiologically relevant, is persuasive.

Differentiation antigens

Tumors may express antigens normally expressed during the developing cells of the parent tissue, examples being the wide variety of lymphocyte antigens expressed on lymphomas, prostate-specific antigen in prostate carcinoma, and thyroglobulin in thyroid carcinomas. Such antigens are clearly not TSTAs but are nonetheless tumor associated and may thus be of use either diagnostically or therapeutically.

Diagnostic relevance of tumor immunology

The use of panels of monoclonal antibodies (mAbs) for immunophenotyping tumor material is now well established and of great value in subtyping lymphomas and for determining the histogenesis of undifferentiated tumors.

Antibodies directed against tumor-associated antigens have also been used for the immunolocalization of tumors by means of radiolabeled antibodies. So far, this conceptually appealing mode of imaging has failed to prove more effective than more conventional imaging techniques.

Therapeutic modification of the immune response

Immune response modifiers

A considerable literature now exists on the use of genetically engineered cytokines in the treatment of cancer. Initial enthusiasm has now abated with the realization that the immune system can not easily be turned on to tumor targets by the indiscriminate activation of the immune system by cytokines such as IL-2 and interferon α . However, interferons do have a defined role and proven efficacy in the management of certain conditions, particularly melanoma, renal cell carcinoma and hairy cell leukemia and as adjuvant therapy in certain hematological malignancies such as low-grade lymphoma and myeloma.

Interleukin 2 was first used in studies at the National Cancer Institute in the mid-1980s and attracted widespread attention as a potential breakthrough in the treatment of renal cell carcinoma and melanoma. Studies elsewhere have confirmed an effect in these tumors but only in a small number of patients and at high cost in toxicity. The *in vitro* expansion of cells from tumor samples, generating tumor-infiltrating lymphocytes (TILs), or peripheral blood to produce lymphokine-activated killer (LAK) cells, probably does not usefully increase the response rate. The combination of IL-2 with interferon and chemotherapy may increase the response rate although at present the high toxicity makes the routine use of IL-2 outside study settings in specialist units inadvisable.

Both IL-2 and interferon α , used as sole therapy for metastatic melanoma or renal cell carcinoma, produce response rates of 5–40% depending on patient selection criteria. In essence, fit patients with a low disease burden (and prior nephrectomy in the case of renal cell carcinoma) are most likely to respond to either agent. Some metastatic sites (e.g. lung) respond better than others (e.g. bone or liver). However, the median duration of response is generally less than a year and long-term survivors rare. Nonetheless, spectacular responses, and long-term survivors do occasionally occur with immunotherapy in a few lucky cases. Furthermore, these malignancies, whilst in some ways unusual, are not typically associated with immunosuppression, suggesting that they are able to evade an intact immune system but that this evasion can be surmounted. The search is thus continuing for ways of improving the response rate by more effective targeting of such therapies (see below).

Monoclonal antibodies

The development of monoclonal antibody technology also generated a wave of enthusiasm for these seemingly ideal anticancer agents – natural, nontoxic and exquisitely targeted. Unfortunately, problems of delivery to targets, reactions to murine antibodies and difficulties in the linking of suitable warheads to these biological 'guided missiles' prevented them from fulfilling their initial promise. There appear to be three problems preventing effective therapy: the first is dissociation of the antibody from its 'warhead'; the second is the therapeutic ratio between nonspecific binding (especially to lymphoid tissue) and target tumor tissue; the third is the development of a host response against the antibody, which is usually of murine origin and which limits the number of repeat treatments that may be given.

The problems are all amenable to at least partial

solution. For example, the use of F(ab)₂ fragments of 'humanized' mAbs may abrogate the nonspecific binding and host response problems. Improved chelation techniques may decrease the extent of complex dissociation. Other areas of research include the use of mAbs linked to enzymes which are then used to activate an inactive prodrug – antibody-directed enzyme prodrug therapy (ADEPT). This approach has the additional advantage that the half-life of specific binding is usually much greater than that of nonspecific binding, thereby improving the therapeutic ratio as administration of the active drug can be delayed to allow clearing of such nonspecifically bound antibody. By means of such approaches, it may become possible in the future to utilize mAbs for systemic therapy, probably as an adjunct to more conventional debulking treatment such as surgery, radiotherapy or chemotherapy although the clinical utility of ADEPT remains to be convincingly demonstrated.

A new generation of bispecific antibodies (BSABs) may circumvent some of these problems by aiming to cross-link targets to immune effector cells to initiate a cell-mediated antitumor response. This circumvents the problems of cross-linkage as stable covalently BSABs can be formed. Delivery is less of an issue than when the mAb is the primary effector molecule due to 'bystander' lysis of adjacent cells by activated immune cells. Promising results have been observed with BSABs given with recombinant cytokines in phase I/II trials using antibodies targeted to the HER2/NEU gene product and the macrophage Fcγ receptor.

Monoclonal antibodies have been used extensively to purge marrow for autologous bone marrow transplantation (ABMT), though with little direct evidence to support its use. Recent evidence from the Barts lymphoma ABMT program suggests that, at best, a 2 log cell kill can be obtained by treatment with a single monoclonal antibody, but that complete clearance of abnormal cells (measured by polymerase chain reaction amplification and detection of the t(14,18) translocation breakpoint region) only occurred in those with the lowest initial burdens. The significance of these results remains unclear.

Immune factors also play a role in the success of allogeneic transplantation for leukemia. Graft-versus-host disease (GVHD) is a major clinical problem, predicted by the classical adoptive transfer experiments of Billingham, Brent and Medawar. Unfortunately, attempts to reduce GVHD, for example by T cell depletion of donor marrow, resulted in increased leukemic relapse rates. Furthermore, patients receiving marrow from identical twins have a higher leukemic relapse rate and, conversely, patients with

severe GVHD a lower relapse rate, suggesting a significant graft-versus-leukemia effect. Thus, post-transplant immunosuppression protocols tread a wary balance between these two conflicting problems.

Cancer vaccines

The last 10 years have seen dramatic advances in our understanding of how human T lymphocytes recognize and in some situations destroy cancer cells. Major efforts are going into the development of various types of cancer vaccines using peptides, glycoproteins, antibody idiotypes as well as autologous tumor cell lines. Polynucleotides encoding for various tumor specific peptides have been claimed to raise a powerful immune response under certain situations.

Recently, the successful cloning of cytolytic T cells (CTLs) has led to the identification of a series of antigenic peptides degraded from intracellular proteins and ending up in the clefts of MHC molecules on the external surface of the cell. Three approaches have been used in their identification. Target cells transfected with cDNA libraries have been used to analyse specificity of CTL clones. This genetic approach was used to identify the MAGE series of melanoma antigens as well as MART, tyrosinase and melan-A. A biochemical strategy has been the separation and characterization of peptides from purified MHC molecules. A third approach has been the construction and analysis of the response to synthetic peptides that bind to MHC class I determinants.

Phase I clinical trials are now in progress using several vaccine strategies (Table 1). Most involve direct peptide injection with immunological adjuvant but enhanced responses may be obtained by using autologous dendritic cells pulsed with peptide antigens. Assays are available to measure the immunological effectiveness of such vaccines so that optimization can be achieved before moving to larger scale phase II trials aimed at determining efficacy.

Gene therapy

As outlined above, there is increasing evidence that tumor cells do express antigens not found on the parent normal tissue. Evidence from studies using cytokines such as interleukin 2 and interferon α demonstrate that in both experimental and clinical settings, the immune system can be stimulated to recognize and destroy tumor targets. Considerable recent research has thus focused on possible reasons why tumors escape elimination by the immune system. If the principal reason for the lack of an effective immune response is related to defects in immune processing rather than a lack of identifiable targets *per se*, then manipulation of the immune process may allow effective immunotherapy on a wider scale than hitherto has appeared possible.

There has been much recent interest in modifying tumors to make them more immunogenic. Experiments using nonimmunogenic animal tumors such as the B16F10 melanoma cell line have shown that modification of tumor cells to express the coimmunostimulatory molecule B7-1 will result in subsequent rejection of challenge with both modified and unmodified tumor cells. Similar results have been obtained with interleukin 12, which is also involved at a key initial stage of initiation of the cell-mediated immune response. However, although dramatic results have been obtained in certain well-defined models, there is also increasing evidence that single modifications to render tumors immunogenic are unlikely to be sufficient to overcome the profound inability of the immune system to recognize and eliminate most human tumors. Nonetheless, combination approaches utilizing genetic modification of targets, cytokines and linking molecules such as BSABs may in the future be able to deliver effective targeted anti-tumor immunotherapy.

Conclusions

There are many potential permutations for the application for immunologically based therapy for cancer. One of the most important developments has been the increased understanding of the molecular mechanisms of malignancy through which biological manipulation can be tailored to an individual tumor. Although current clinical studies are not demonstrating high response rates, there remain tantalizing pointers towards more effective therapies in the future.

IMMUNOTOXICOLOGY

Michael I Luster and **Petia P Simeonova**, Toxicology and Molecular Biology Branch, Health Effects Laboratory Division, National Institute for Occupational Safety and Health, Morgantown, West Virginia, USA

Dori R Germolec, Environmental Immunology Section, National Institute of Environmental Health Sciences, NIEHS, Research Triangle Park, North Carolina, USA

Immunotoxicology has been defined as the study of adverse effects on the immune system resulting directly or indirectly from occupational, environmental or therapeutic exposure to chemicals (including drugs), biologic materials and, in certain instances, physiological factors, collectively referred to as agents. It encompasses studies of altered immunologic events associated with exposure of humans and wildlife species including immune regulation (suppression or enhancement), allergy and autoimmunity (**Figure 1**). In the former case, the systemic or local (e.g. skin, lung) immune system acts as a passive target for the agent, and the result may be an increased incidence or severity of infectious disease or neoplasia. In allergy, the immune system responds to chemical (hapten)–host protein conjugates or high molecular weight compounds. The most likely health consequences of the latter include respiratory tract allergies (e.g. asthma, rhinitis) or allergic contact dermatitis. Autoimmunity may occur either as a result of an agent-induced alteration in host tissue, endocrine function or immune regulation. More recently, studies in immunotoxicology have also included investigations into the role of inflammatory mediators, particularly cytokines and reactive oxygen species, in localized chemical toxicities as many of these mediators are produced by and/or act upon immune cells.

The potential for adverse health effects due to alterations in the immune system by toxic agents has been a matter of increasing scientific and public concern. As such, there have been marked efforts in both basic research undertaken within this area as well as development and incorporation of appropriate test methods to assess potential immunotoxicities in experimental animals, wildlife species and humans. Regarding testing methods, appropriate selection has been complicated by the need to employ distinct tests based upon the site examined (e.g. systemic, lung, skin) and the immunopathology of concern (i.e. hypersensitivity, immune regulation, autoimmunity, inflammation). However, our increased understanding of the molecular, cellular and genetic events responsible for mounting appropriate immune responses, as well as for the immune mediators

involved in organ-specific necrotic and apoptotic processes, has provided opportunities for the utilization of more streamlined and informative tests for risk assessment and the development of novel preventive or therapeutic measures.

Hypersensitivity

Pharmacologically mediated hypersensitivity responses, such as those elicited with β -lactam antibiotics, are well recognized. In addition, a number of industrial materials have known or presumed allergic activities in humans and laboratory animals (**Table 1**). This response can be mediated by T cells as well as antibodies (e.g. IgE) and can result in allergic contact dermatitis or allergic lung disease (asthma). A compound causing both these responses is toluene diisocyanate (TDI), a classic representative of the isocyanate compounds used in the production of plastics and resins. TDI, which acts as a hapten, is particularly reactive with amino groups on proteins. Chemical-induced allergic respiratory responses can also be induced by high molecular weight compounds from animal urine and saliva, enzymes in detergent, plant materials as well as therapeutic peptides. Clinical differentiation of allergic responses from nonimmune irritant responses, without detecting specific immune responses, are often difficult, but the former are usually more persistent and severe.

Tests to identify potential respiratory sensitizers are difficult to undertake and, as such, efforts to validate screening models are limited. Although the guinea pig has some significant immunological differences compared to humans (e.g. IgG1 versus IgE reagenic antibodies), it has proved a predictable animal model for humans given the limited comparative data available and has been used to test for both low and high molecular weight sensitizers. As with guinea pig skin tests, the method includes both an aerosol sensitization and challenge phase. There is also a need to measure both immediate and delayed-onset responses, although this does not distinguish between nonspecific pulmonary hyperreactivity and specific immune responses. The latter is commonly

Figure 1 Scheme for direct or indirect effects of xenobiotic agents on the immune system and potential outcomes. (Reproduced with permission from Karrow JG and Holsapple MP (1995) Structure and function of the immune system. In: Smialowicz R and Holsapple M (eds) *Experimental Immunotoxicology*, pp. 3–12. Boca Raton, FL: CRC Press.

established by examining sera for the presence of reagenic antibodies.

Historically, the guinea pig has also been used to test for potential skin sensitizers and such tests have been incorporated into many regulatory guidelines. Many variations in guinea pig hypersensitivity assays exist, but the Buehler occluded and Magnusson–Kligman maximization tests have been most often employed. Because guinea pigs are large, several graded doses of antigen may be tested and an entire dose–response curve can be generated by comparing skin reactions in individual animals. However, it is expensive to purchase as well as maintain guinea

pigs, there are few inbred strains and immunological reagents are not widely available. As such, efforts are presently underway to replace guinea pig assays with mouse models. The most promising test is the local lymph node assay (LLNA). This procedure allows for the quantitation of lymphocyte proliferation in lymph nodes draining the site of chemical application, which is routinely the ear, and compared to guinea pig assays, is considerably less complex and time consuming. The LLNA may fail to detect some weak sensitizers and provide false positives for strong irritants, but modifications of the assay have been used, such as skin abrasion, to increase the

Table 1 Examples of agents reported to be immunotoxic

<i>Hypersensitivity</i>	<i>Immunosuppression</i>	<i>Autoimmune-like^a</i>

^aAutoimmune like = the symptoms disappear when the offending agent is removed.

sensitivity. These procedures can also be modified to allow examination of potential photoallergens.

Autoimmunity

The well-documented examples of drug-induced autoimmune-like syndromes have led to studies to determine whether certain agents contribute to the incidence of autoimmune diseases. Some of the chemical and therapeutic agents suggested to be associated with autoimmune diseases or autoimmune phenomenon (i.e. increased levels of autoantibodies), in experimental animals or humans are listed in **Table 1** and include several heavy metals, pharmaceuticals, organic solvents and foods. As a number of factors participate in the development of autoimmune disease and it presents both diverse clinical symptomology and organ specificity, appropriate animal models have been difficult to develop. One method that has received attention is the popliteal lymph node assay (PLNA) which measures proliferative activity in the draining lymph nodes. Although this assay appears to detect low molecular weight compounds with immunomodulatory potential, it does not necessarily discriminate those that influence autoimmunity and may provide false positives with irritating agents. A number of animal models for autoimmune diseases exist, such as immunization (e.g. with myelin basic protein for multiple sclerosis) or animals that develop spontaneous autoimmunity. However, their evaluation as screening models in immunotoxicology has not been sufficiently investigated. A large database exists on animal strains with

genetic susceptibility to autoimmune disease from exposure to metals, such as cadmium or mercury, and include the Brown-Norway rat, ICR mouse and H2^s mouse. Silicone, used in surgical implants, has recently been implicated in autoimmune phenomena in humans, although epidemiological data clearly do not support such a relationship. This, however, does not preclude the need to have available predictable testing methods for detecting such agents and, in fact, may exemplify the need for such assays.

Immune regulation

Although immune regulation (i.e. suppression or stimulation of the local or systemic immune response) may represent a potentially more significant human health hazard than hypersensitivity and, as such, has been afforded considerable attention. Initially, efforts were made by immunologists working in this area of toxicology to identify agents which could potentially alter the immune system using various *in vitro* or rodent models (i.e. hazard identification). Subsequently, studies were conducted to develop more predictive test methods, determine mechanisms of action, or identify affected human populations. Based primarily upon animal studies, a number of agents have been shown to alter regulation of the immune system (**Table 1**). One of the most studied classes of chemicals are halogenated aromatic hydrocarbons, which include dioxins and polychlorinated biphenyls (PCBs). 2,3,7,8-Tetrachlorodibenzo-*p*-dioxin (TCDD), a prototype of this class, is a potent immunotoxic chemical in mice with an ED₅₀ for antibody suppression of 1–2 µg kg⁻¹ body weight.

Although the exact mechanisms by which TCDD exerts its immunotoxicity has not been established, it is known to affect a number of immune cell types, to alter differentiation processes (possibly via altering tyrosine kinase activity) and to require binding to an intracellular receptor (referred to as the Ah-receptor for aromatic hydrocarbon). Once bound to the receptor, the complex is capable of translocating to the nucleus and interacting with 'dioxin responsive elements' on DNA that help regulate expression of numerous genes. Although immunological changes have been reported in human and wildlife populations exposed to dioxins and/or PCBs, the significance of these findings are hotly contested. One view states that the reported immune changes are not of sufficient magnitude to be considered relevant biologically. This conclusion is supported by the lack of clear evidence that the exposed populations show increased frequencies of immune-associated diseases such as infections. The opposing view states that

even small changes in the immune system can translate to increased frequency or severity of disease, but the ability to discern this is dependent upon the size of the population exposed and how closely they are monitored. Thus, while the immune system may be redundant, it does not possess significant reserve. The latter hypothesis is supported by mathematical models derived from experimental data bases. Data bases to conduct similar types of analysis do not exist in humans. A recent study by Weisglan-Kuperus and colleagues, exemplifies the debate. In this report, a dose-response relationship was observed between TCDD/PCB internal exposure and significant changes in cell surface markers, particularly, CD3⁺CD8⁺ T cells in infants exposed via breast milk. Similar observations were reported previously in mice and nonhuman primates receiving chronic, low-level dioxin exposure. The infants, however, showed no evidence of increased disease and the phenotype values fell within background levels which can show a coefficient of variation as high as 30%. The significance of such findings will probably be argued until improved disease monitoring and use of standardized methods are evoked.

Incorporating experimental animal data on toxicant-induced immune alterations as part of the evaluation of drugs and chemicals in human risk assessment has become increasingly common. Because of the complexity of the immune system, the initial strategies devised by immunologists working in toxicology and safety assessment have been to select and apply a tiered panel of assays to identify hazardous agents. These tests included both functional and non-functional (e.g. lymphoid organ histology) assays, as well as host resistance tests. More recently, it has been shown that only a minimal number of appropriate tests need be conducted for general immune screening. As such, both regulatory agencies and industry are now requiring or recommending (i.e. on a needed basis) immune system evaluation. A surprising exception to this is the Center for Biological Evaluation and Research of the Food and Drug Administration, which is responsible for testing biological materials including immunoregulatory cytokines and growth factors, and support the notion that in immunotoxicity issues should focus only on antigenicity. A general screening approach which is increasingly being required by many agencies and private industries involves the examination of lymphoid organs (e.g. histology, organ weight) and a functional assay requiring the quantitation of antibodies following immunization with sheep erythrocytes in rodents exposed to the test agent. The latter assay has undergone extensive validation studies and

appears to be a predictive and sensitive indicator for most immunotoxic agents.

Local immunity

As the portal of entry for many agents is the lung or skin, attention in immunotoxicology has also been directed to assessing local immunity at these sites. In the lung, for example, there is growing clinical evidence suggesting that nonspecific and specific immune mechanisms play a major role in pulmonary diseases associated with air pollutants including oxidant gases, such as ozone and nitrogen oxides, as well as particulates such as silica, asbestos and coal dust. For the most part, these appear to be associated with the synthesis and release of proinflammatory cytokines from alveolar macrophages and lung epithelial cells. Recent studies have also established immune-mediated mechanisms associated with the development of certain occupational pneumoconiosis (disorders caused by inhalation of particulates or aerosols) such as berylliosis (beryllium), byssinosis (cotton dust), and occupational asthmas (red cedar). Although validated methods to screen pulmonary immunotoxicants are not available, cellular and biochemical profiles of bronchoalveolar lavage constituents following inhalation exposure in experimental animals and humans can be useful for determining immune-mediated lung injury. These include, in addition to examining cellular infiltration and the release of cytokines, quantifying a variety of short-lived products which contribute to altering resistance to pulmonary infections and inflammation including arachidonic acid products and reactive oxygen species. Other immunological defenses operating in the lung include humoral- and cell-mediated immunity derived from bronchial-associated lymphoid tissue (BALT), as well as interstitial lymphocytes. The lung also possesses natural killer (NK) cells which are affected by a number of agents including phosgene. The overall alterations of such systems by these agents has been shown to play a role in respiratory infections, asthma severity, granulomatous lung disease and even interstitial pulmonary fibrosis.

Similar to the lung, mammalian skin is in contact with draining lymph nodes and contains immune components, including Langerhans cells, cytokine-producing keratinocytes and T lymphocytes. Skin-associated lymphoid tissue can respond to agents by the induction of allergic contact dermatitis or by induction of local or systemic (antigen-specific) immunosuppression. Immunosuppression can occur following dermal exposure to ultraviolet radiation and chemicals, such as polycyclic aromatic hydrocarbons. The mechanisms for this are complex but

appear to involve the release of soluble mediators from keratinocytes, including regulatory cytokines. Although *in vitro* tests are available for screening contact irritants, which often involve monitoring the release of inflammatory mediators, there are no standardized methods available for assessing altered skin immunity.

As a subdiscipline of toxicology, immunotoxicology studies are providing valuable information in risk assessment for humans and, to a lesser extent, wildlife. To improve risk assessment, however, it will be necessary to develop more sensitive human and wildlife epidemiological and immunological biomarkers, determine sensitive populations and better understand the quantitative relationships between changes in immune function and disease.

INBRED STRAINS

Michael FW Festing, MRC Toxicology Unit, University of Leicester, Leicester, UK

According to Grunberg in 1952: 'The introduction of inbred strains into biology is comparable in importance with that of the analytical balance into chemistry.' While this is open to debate, there is little doubt that inbred strains have made a substantial contribution to the advance of biomedical sciences. Several Nobel Prizes in immunology (e.g. Medawar and Snell) have been for work which would have been difficult, or impossible, without using such strains.

Definition

For most practical purposes, an inbred strain can be regarded as an immortal clone of genetically identical individuals. According to the International Committee on the Genetic Nomenclature of the Mouse:

A strain shall be regarded as inbred when it has been brother $\times$ sister mated (hereafter called b $\times$ s) for 20 or more consecutive generations (F20), and can be traced back to a single ancestral breeding pair in the 20th or subsequent generations. Parent $\times$ offspring matings may be substituted for b $\times$ s

matings provided that, in the case of consecutive parent $\times$ offspring matings, the mating in each case is to the younger of the two parents.

Similar definitions apply to other species.

Brother $\times$ sister mating increases homozygosity at each gene locus at about 19.1% per generation. So a strain is never fully inbred, but homozygosity exceeds 98% after 20 generations. Eventually, an equilibrium is set up between the loss of heterozygosity due to continued inbreeding, and the generation of new genetic variation by mutation. A single breeding pair in the 20th or a subsequent generation is chosen to ensure that the strain is also isogenic, i.e. all individuals are genetically identical (see below). Where parent $\times$ offspring matings are necessary, the younger of the two parents is used to avoid several generations of backcrossing to a single individual, which is not genetically equivalent to brother $\times$ sister mating.

Most of the common inbred strains of mice and rats were developed between 1906 and about 1940, though a few strains continue to be developed each

year. For example, the most widely used strains of mice are C57BL, C3H, CBA, BALB/c, and AKR, which were all developed between 1920 and 1936. Several strains (including C3H and AKR) were selected for a high incidence of neoplasia. Currently there are over 400 inbred mouse and 200 inbred rat strains (many more if congenic and recombinant inbred strains are also counted), but only a handful of inbred strains of guinea pigs, hamsters, gerbils, chickens and rabbits.

Derivatives of inbred strains

A pair of strains are said to be coisogenic when they differ at a single genetic locus as a result of a mutation within one branch of an inbred strain. Congenic strains are inbred strains of mice and rats approximating the coisogenic status, developed by 12 or more backcrosses of a gene to an inbred strain. They may carry 'passenger' genes closely linked to the backcrossed gene. Sets of recombinant inbred strains (RIS) are developed by brother $\times$ sister inbreeding from the F1 hybrid between two standard inbred strains. If 7–20 or more such strains can be developed from a single cross, and each strain is phenotyped, the resulting strain distribution pattern can be compared with that already determined for other genes in the same RIS set. A close match would imply genetic linkage.

Recombinant congenic strains are produced by crossing two inbred strains, followed by 1–6 generations of backcrossing, then brother $\times$ sister mating. The resulting set of 20 or more strains is useful in the genetic analysis of polygenic characters and the identification of quantitative trait loci (QTLs).

Transgenic (including knockout) strains are developed by transferring DNA to an individual, typically at the preimplantation embryo stage. Inbred knockout strains are similar to coisogenic strains, with a single mutant locus. Inbred transgenic strains other than knockouts are also similar to coisogenic strains except that the DNA may have become integrated as tandem arrays of several copies of the foreign DNA in a 'random' location in the host genome.

The first-generation offspring of a cross between two inbred strains is known as an F1 hybrid. These are isogenic, though heterozygous at all loci at which the two strains differ (see below for the properties of inbred strains). They also tend to be more vigorous and robust than either parental strain as a result of hybrid vigor.

Nomenclature

Full details are given in *Genetic Variants and Strains of the Laboratory Mouse*, 3rd edn (see Further reading). Inbred strains are designated by a capital letter or letters (e.g. CBA, SJL), or less preferably by a combination of letters and numbers beginning with a letter (e.g. C3H, C57BL). Most designations have little or no meaning. The use of long strain names such as 'Brown Norway' instead of BN is not encouraged.

Where necessary, the number of generations of brother $\times$ sister mating can be indicated by appending an F followed by the number of inbred generations (e.g. F31). If, because of incomplete records, the number indicates only part of the inbreeding, this should be indicated with a question mark (e.g. F?+31).

Two colonies of the same strain would be regarded as substrains if there were known or probable genetic differences between them, as a result of residual heterozygosity at the time of separation (remember, no strain is ever fully inbred), or as a result of new mutations. Colonies separated between F20 and F40, and those separated from a common ancestor for more than 100 generations should be considered as substrains. Substrains are designated by a slash, followed by a substrain symbol, which can be a number or letter(s) indicating the name of an investigator or laboratory, or a combination of the two (e.g. DBA/1 and DBA/2, C3H/He and C3H/Bi).

Environmental, maternal or cytoplasmic factors may also alter strain characteristics. Cross-fostering, embryo transfer or ovarian grafting may alter the complement of vertically transmitted retroviruses. Hence, in addition to any substrain symbol, a laboratory code should be appended to the strain name following an @ symbol (e.g. C3H/He@N, mice of the C3H/He strain and substrain bred at the National Institutes of Health) in order to indicate the laboratory of origin and to emphasize the fact that even genetically identical animals may differ as a result of nongenetic factors.

Maintenance of inbred strains

The aim is usually to keep the strain genetically constant with an easy and efficient breeding protocol. A self-supporting stem line colony of 10–40 breeding pairs, which are mated brother $\times$ sister, can provide breeding stock for one or more expansion colonies of several hundred breeding pairs. These may be mated at random for 2–3 generations without any deleterious consequences, provided the strain is fully inbred to F >20.

Genetic quality control or genetic monitoring is essential as a single nonstrain mating can destroy an inbred strain. The following methods have proved useful, though the last method is likely to be most widely used in future.

Skin grafting

Skin grafts between members of the same strain should not be rejected. This provides a way of testing for isogenicity, and genetic contamination by a non-strain mating. However, it cannot easily be used to confirm that the strain is AKR rather than BALB/c (both of which are albino), and it takes 5–6 weeks to ensure that grafts are not rejected due to a weak incompatibility.

Protein polymorphism

Polymorphic loci, in which different alleles can be detected electrophoretically, can be used as genetic markers. For example, strain C57BL carries the Hbb^s allele, and DBA/2 carries the Hbb^d allele coding for the hemoglobin β chain. These give a single and a double band on the gel, respectively, following electrophoresis of a red blood cell lysate. The disadvantage is that these biochemical methods require considerable skill, and will not normally distinguish between congenic strains which differ, say, only at the major histocompatibility complex (MHC).

Serological methods

A strain-specific alloantiserum can be produced by injecting lymphocytes from 5–10 different strains with various lymphocyte alloantigens into animals of the strain to be monitored in the future. Such an antiserum will not react with lymphocytes from the host strain, but will usually react with lymphocytes from other strains. Similar serological methods can be used with monoclonal antibodies to detect the presence of polymorphic alloantigens (e.g. on lymphocytes), which can be compared with published data for the strain.

DNA polymorphisms

DNA fingerprinting, DNA probes for minisatellite loci and restriction fragment polymorphisms offer powerful methods for genetic quality control. However, 'microsatellite' markers appear to be even more convenient for most purposes. More than 6000 microsatellite markers identifying specific locations on all chromosomes have been described and mapped in the mouse, and a similar number will be available soon in the rat. These are highly polymorphic in the number of repeats, and can be detected

rapidly using the appropriate primers and the polymerase chain reaction followed by gel electrophoresis. These provide a powerful tool for genetic quality control, requiring only very small quantities of DNA. Data on microsatellites are available by e-mail (see Further reading).

Properties of inbred strains

The properties of these strains can be briefly described as follows.

Isogenicity All individuals of an inbred strain are genetically identical at all but a handful of loci. The consequence is that a single individual of the strain can be typed, say at the MHC or a microsatellite locus, and this will serve to type all members of the strain. In this way, a genetic profile of the genes present in the strain can be built up and used in the planning and interpretation of experiments. Isogenicity also ensures that cells, tumors and organs can normally be exchanged within a strain without immunological rejection. It also ensures that a new colony established from one or more pairs will be an exact genetic representation of the parent colony. This is not the case with a noninbred colony, where an individual only has a sample of the genes present in the colony.

Homozygosity Each inbred individual is homozygous at almost all loci. There are no 'hidden' recessive genes which are not expressed because of the presence of their normal allele. Within-strain matings should breed true, with all offspring genetically identical to the parents, apart from any new mutations that might occur. Note that F1 hybrids are heterozygous at all loci at which the parental strains differed, hence F1 hybrids will not breed true.

Phenotypic uniformity Isogenicity leads to phenotypic uniformity, in the same way that pairs of identical twin humans are more similar than pairs of random individuals. One consequence is that, usually, fewer animals are needed to achieve a given level of statistical precision in an experiment than if outbred animals are used.

Long-term stability In inbred strains, the frequency of all alleles is fixed at zero or one. Genetic change can only occur as a result of residual heterozygosity, or the occurrence of new mutations. Thus inbred strains stay constant for long periods of time, allowing the accumulation of background information which can be used in the planning and interpretation of experiments.

Identifiability Once the genetic profile at a number of polymorphic (e.g. microsatellite) loci is known, this information may be used to identify the strain. In contrast, there is no way of checking the genetic authenticity of outbred stocks such as Wistar rats or Swiss mice.

Sensitivity Inbred strains are more sensitive to adverse environmental conditions than are outbred stocks, so must be maintained under good conditions.

International distribution Because of their long-term stability, isogenicity, identifiability and homozygosity, colonies distributed throughout the world will stay very similar to the parental colony for several years, so research done on such strains is comparable. In contrast although outbred 'Wistar' rats or 'Swiss' mice (for example) have an international distribution, each colony is in fact genetically unique.

Individuality Each inbred strain represents a unique combination of genes at about 30 000 different genetic loci, resulting in a unique phenotype. For example, there are strains with a high and others with a low level of spontaneous tumors, immune responses to particular antigens, spontaneous activity or relative brain weight, to give just a few examples. Care must be taken to ensure that the chosen strain is suitable for the particular experiment.

Fitness

During the process of inbreeding, some deleterious genes become fixed in a strain. As a result, inbred strains tend to be less vigorous, and have a poorer breeding performance than outbred stocks. F1 hybrids show hybrid vigor and are generally fitter as a result of deleterious recessive genes being 'covered up' by more advantageous genes present in one or other of the parental strains.

Research uses

Some experiments, such as those involving the transfer of cells or tissues between individuals without immunological rejection, can usually only be done with inbred strains or immunodeficient strains (which are not always easy to maintain). In other

cases, comparison of the responses of two or more strains, particularly if the strains differ at a relevant genetic locus, can be highly informative.

There are a few experiments for which inbred strains are unsuitable. In some cases, their use is rejected because they are more expensive than outbred animals, though this may be a false economy. They may be unsuitable for experiments which require a very good breeding performance, and for certain genetic experiments such as those aimed at changing strain characteristics by selection. Generally, the advantages of inbred strains are so overwhelming that, where available, they should be used for all research unless a case is specifically made to use an alternative type of stock.

INFERTILITY, IMMUNOLOGICAL CAUSES OF

Tage Hjort, Department of Medical Microbiology and Immunology,
University of Aarhus, Aarhus, Denmark

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

According to the common definition of infertility, a couple is regarded as being infertile if conception has been pursued unsuccessfully for 2 years or more. The incidence of infertility varies in different parts of the world. In Western countries it has been estimated that 12–15% of all couples eventually experience infertility, either primary or secondary in nature. Besides a general physical examination, investigations of infertile couples include semen analysis and tests for ovulation and tubal function. However, in 12–25% of cases, these basic investigations reveal no significant abnormalities, and such cases are commonly referred to as ‘unexplained’ infertility.

Since the 1950s, autoimmune responses to organ-specific reproductive tract antigens in both males and females and so-called isoimmune reactions of females towards components in semen have been extensively studied as possible causes of ‘unexplained’ infertility, leading to the conclusion that immune responses may cause or contribute to the infertility in about 10% of these couples.

Immunity to semen

Semen contains a multitude of antigens, in seminal plasma as well as in sperm. Some overlap between the two groups of antigens exists because some seminal plasma antigens adhere so firmly to the sperm membrane that they cannot be removed by washing (sperm-coating antigens). However, not all of these antigens are semen specific and only some are able to induce auto- or isoimmunity. A glycoprotein in seminal plasma may rarely induce immunoglobulin E (IgE) antibodies in women, causing severe anaphylactic reactions immediately after exposure to semen. More important, sperm-immobilizing antibodies to a sperm-coating carbohydrate antigen (N-acetylglucosamine) have been found in about 15% of women with unexplained infertility in Japan, but apparently not in other parts of the world. The possibility that the immune response might be caused by a cross-reacting microorganism has therefore been discussed.

The sperm-specific autoantigens are listed in **Table 1** together with some of the techniques used to detect the corresponding autoantibodies. More recently, by means of monoclonal antibodies a number of sperm-specific antigens implicated in gamete interactions have been identified and characterized, e.g. PH-20,

Table 1 Autoantigens in human sperm

<i>Antigen</i>	<i>Localization</i>	<i>Detection of antibodies</i>
Glycoproteins (3 or more)	Membrane in intact sperm	Immunobead test, MAR, agglutination and immobilization tests
LDH-C4, acrosin, hyaluronidase	Enzymes in the acrosome	Radioimmunoassay (for LDH-C4)
Protamine 1 and 2	Sperm nucleus	Immunofluorescence on swollen sperm heads
Various poorly characterized subsurface antigens	Acrosome, equatorial segment, postnuclear cap, main tail piece, tail end-piece	Immunofluorescence on fixed spermatozoa

FA-1, SP-10, but is not yet clear to what extent they are true autoantigens.

For many years, sperm antigens were considered sequestered, i.e. normally secluded from contact with immunocompetent cells and thus unable to induce immunological tolerance. This theory has now been questioned, and local immunoregulatory factors have been assumed to play a role in preventing immune responses. Nevertheless, sperm-reactive antibodies are quite often present in human sera. Using the immunoblotting technique, nearly 50% of male and female sera have been found to react with at least one band, but since reactions are observed as frequently with sera from fertile as from infertile persons, most of these antibodies are obviously of no interest in relation to fertility. So far, only immune responses to the membrane glycoproteins (i.e. the antigens which are accessible for antibody binding in intact sperm) have been closely linked with subfertility or infertility.

Also lactate dehydrogenase C4 isoenzyme (LDH-C4) is expressed in the sperm membrane, and in immunization experiments with mice, rats and baboons, high levels of LDH-C4-specific antibodies have been found to interfere with female fertility. However, the significance of such responses in humans has not been clarified. By means of a sensitive radioimmunoassay, modestly elevated levels of antibodies reacting with LDH-C4 have been detected

in about 10% of males and females with unexplained infertility.

Antibodies to sperm membrane antigens

The occurrence of sperm-specific antibodies in 60–70% of vasectomized men shows that occlusion of the efferent ducts can induce autoimmunity, and infections may also stimulate immune responses, possibly through an adjuvant effect. However in most cases no explanation for the immune response can be found.

Male laboratory animals immunized with homologous sperm in complete Freund's adjuvant develop orchitis with destruction of the germinal tissue, but in men the autoimmunity apparently does not affect spermatogenesis. Apart from modest deposits of immunoglobulin around seminiferous tubules, testicular histology has been normal in most men with sperm-specific antibodies who (for other reasons) have had testis biopsies performed, and semen samples often show normal sperm counts and normal motility. However, the presence of antibodies on motile sperm can be demonstrated by simple techniques such as the immunobead-binding test, in which particles covered with anti-immunoglobulin attach to the sperm, or the rather similar mixed antiglobulin reaction (MAR). The use of class-specific anti-immunoglobulins in these tests has led to the observation that IgA antibodies (but not IgG antibodies) impair or inhibit the migration of sperm through cervical mucus. Sperm covered with IgA are seen to shake vigorously in the mucus without forward progression. This explains the strong fertility reducing effect of locally produced IgA antibodies in semen or cervical mucus.

The significance of IgG antibodies, which predominate in serum and are transudated to semen (1% of serum concentration), is less clear, because in men from infertile couples IgG antibodies are rarely found without IgA antibodies also being present. The percentage of eggs being fertilized by *in vitro* fertilization (IVF) is usually reduced when the sperm reveal strong immunobead or MAR reactivity, but also here IgA may be playing the major role. *In vitro* experiments with human IgG antibodies have indicated that in certain cases they could block fertilization, but on the other hand vasovasostomized men with only IgG anti-sperm responses have been found to have the same high fertility rate as vasovasostomized men without sperm-specific antibodies. The explanation why responses with only IgG antibodies are rarely seen among men from infertile couples might therefore be that such men usually do not end up in infertility clinics!

Evidence of immunological subfertility or infertility, i.e. strong IgG and IgA reactivity in immunobead test or MAR combined with detection of free antibodies in seminal plasma or high titers in serum, is found in approximately 10% of the men from couples with unexplained infertility.

In women, most laboratories have found sperm-specific antibodies in serum to be rare and generally present only in low titers. The explanation seems to be that women are exposed only to sperm mixed up with seminal plasma, which contains potent immunosuppressive factors, some of which adhere to the sperm membrane as sperm-coating substances. A multilaboratory study revealed significant immune responses in only 2% of women from couples with unexplained infertility. Detection of antibodies in liquefied cervical mucus (e.g. by indirect immunobead test) seems more informative, particularly since antibodies can apparently occur in cervical mucus without being detectable in serum.

High-dose corticosteroid therapy – with a 30–40% success rate – is now rarely used due to occasional severe side-effects (aseptic necrosis of femoral head). To overcome the impaired migration of IgA-covered sperm through cervical mucus, intrauterine insemination has been used with some success. In cases with strong immunization, IVF may offer the best choice. Although the fertilization rate is usually reduced, once fertilization has occurred the pregnancy rate seems to be the same as for patients without sperm-specific antibodies.

Immunity to zona pellucida

In the mid-1970s, animal studies revealed that the zona pellucida (zp) contains several organ-specific glycoproteins (now known as ZP1, ZP2 and ZP3) and that antibodies to these antigens were capable of blocking fertilization *in vitro*. Human and porcine zp antigens showed cross-reactivity, and interest in this antigen–antibody system was therefore stimulated in 1977 when a high percentage of sera from infertile women by immunofluorescence was found to stain porcine zonae. However, when similar reactivities were subsequently observed, also with sera from fertile females and even with male sera, the specificity of the reactions had to be questioned, and when absorption with pig and human erythrocytes was found to remove the reactivity of most of the sera, serious doubt was raised concerning the presence and clinical significance of zona-specific antibodies. After 20 years and numerous studies there is still no convincing evidence for the occurrence of true zona-specific autoantibodies as the cause of human infertility.

In one of the best controlled studies, with a passive hemagglutination technique using purified porcine zona material for coating of the erythrocytes, weakly positive reactions were recorded in 5.6% of 320 women with unexplained infertility, in 1.7% of 1552 women with infertility of known cause, in 1.5% of 193 fertile women, but in none of 292 men.

In several animal species (dog, rabbit, horse and monkey) active immunization with porcine zona has, on the other hand, produced long-term infertility. The immunization usually also leads to abnormalities in ovarian structure and function with disruption of folliculogenesis and changes in menstrual cycle, and in veterinary medicine immunization with pig zona material is now used to sterilize bitches.

Immunity to trophoblast

Trophoblast-specific antigens have been identified in the syncytiotrophoblast plasma membranes. Therefore, since the surface of the trophoblast is exposed to maternal immunocompetent cells, strong immunoregulatory mechanisms must have been developed during evolution. At the same time as recognition by the maternal immune system of the semi-allogeneic trophoblast seems necessary for the maintenance and growth of the fetus, immune responses to the organ-specific antigens in the trophoblast are apparently effectively prevented. Even though low levels of antibodies reactive with these antigens have occasionally been detected in female sera, there is no

evidence that such responses play a role in infertility. Antibodies to human chorionic gonadotropin (hCG) which, as shown in recent trials of hCG vaccines for immunological contraception, can cause infertility in women, do apparently not occur as 'natural' antibodies.

INFLAMMATORY BOWEL DISEASE

Robert D Fusunyan and **Ian R Sanderson**, Combined Program in Pediatric Gastroenterology and Nutrition, Massachusetts General Hospital, Boston, Massachusetts and Lahey Hitchcock Clinic, Burlington, Massachusetts, USA

Inflammatory bowel disease (IBD) consists of two major illnesses, ulcerative colitis and Crohn's disease, which are chronic disorders of the intestine of unknown origin. Both diseases exhibit chronic inflammatory changes consisting of an intense infiltration of macrophages and lymphocytes with large numbers of plasma cells. In ulcerative colitis, the pathological changes include diffuse inflammation with mucosal ulcers. Involvement is restricted primarily to the mucosa, and not to deeper layers, such as muscle. In Crohn's disease, the inflammatory infiltrate frequently forms granulomas and may extend through all layers of the bowel wall. In both diseases, chronic inflammatory changes dominate the

histological picture. However, Crohn's disease and ulcerative colitis can also exhibit acute inflammatory components. In active inflammatory bowel disease, there is a constant movement of acute inflammatory cells, including neutrophils and monocytes, from the circulation into the inflamed mucosa.

Research into the immunological abnormalities of IBD originally focused on describing alterations in various inflammatory and immune mechanisms. A large body of information has been accumulated over the last 50 years from studying many such factors. More recently, researchers have tried to understand how inflammatory processes are initiated and why the normal mechanisms controlling resolution of

inflammation may be ineffective. While most investigators agree about the inflammatory changes established in the intestine in these conditions, there is still little consensus as to how they are initiated in diseased subjects. Possibilities include an enhanced permeability of the mucosal barrier (Figure 1); inappropriate T cell activation; bacterial and viral etiologies; and vasculitis in the microcirculation of the intestine.

As a host defense mechanism to infectious agents, acute intestinal inflammation is usually self-limiting. However, in ulcerative colitis and Crohn's disease, the normally protective T and B cell immune responses are not appropriately regulated resulting in prolonged activation of mucosal effector cells which may cause damage to the intestine. The immune and inflammatory processes within the intestine may, therefore, exacerbate and perpetuate intestinal injury in inflammatory bowel disease.

Lymphocyte activation

Peripheral blood lymphocytes

Recent studies utilizing monoclonal antibodies against T lymphocytes and their subsets have not

demonstrated any differences between IBD patients and untreated controls. Patients with long-term, steroid-treated Crohn's disease may have lymphocytopenia (particularly T cells), depending on disease duration. However, patients with Crohn's disease exhibit activation markers of peripheral blood T cells in IBD. In one study, the early lymphocyte activation marker, T9 antigen, was expressed by 24% of active Crohn's disease peripheral blood T lymphocytes and by only 10% of inactive Crohn's disease peripheral T lymphocytes. Autoimmune diseases, such as systemic lupus erythematosus and rheumatoid arthritis, were also associated with an increased state of activation of T cells. In contrast, T cell activation was not increased in bacterial or viral colitis. In IBD, a high percentage of activated T9 antigen-positive T cells coexpressed Fc receptors for polymeric immunoglobulin A (IgA), a finding not present in the autoimmune disorders that also exhibited increased peripheral blood T cell activation.

During lymphocyte activation, soluble interleukin 2 (IL-2) receptor molecules may be shed from the surface of T cells or macrophages and serum soluble IL-2 receptor levels are increased in Crohn's disease

Figure 1 Possible activating events in IBD. Bacterial cell wall products, infectious agents and/or toxins can be transported across M cells or presented by class II antigens on epithelial cells to prime and activate macrophages. After antigen presentation, the primed and activated macrophages synthesize and secrete a variety of molecules including proinflammatory cytokines, such as IL-1, IL-6 and TNF α . The proinflammatory cytokines in turn activate a number of cell-mediated events and processes, including activating CD4 $^{+}$ T helper cells in the intestine. In IBD, macrophages and lymphocytes are in a highly activated and upregulated state with the resultant secretion of proinflammatory and immunoregulatory molecules. (Adapted with permission from Reinecker H-C, Schreiber S, Stenson WF and MacDermott RP (1994) The role of the mucosal immune system in ulcerative colitis and Crohn's disease. patients. Crohn's disease peripheral blood mononuclear cells have an enhanced capacity to secrete soluble IL-2 receptor, both spontaneously and after stimulation with phytohemagglutinin (PHA) *in vitro*. The increased capacity of mononuclear cells isolated from intestinal lamina propria to release soluble IL-2 receptor is not specific to IBD because similar findings have been observed in colonic diverticulitis. Nevertheless, increased serum levels of soluble IL-2 receptor in Crohn's disease patients correlate with intestinal inflammatory activity, and the receptor is detected in the portal venous system from inflamed intestine of Crohn's disease patients. These studies, therefore, demonstrate that activated lymphocytes in IBD may be a central feature of the immunological changes that result in inflammation (Figure 2). Measurement of such activation molecules provides a useful marker to correlate the level of tissue inflammation with ongoing disease activity.

Intestinal lymphocytes

Immunohistological studies of the inflammatory cells in IBD mucosa have yielded conflicting results regarding intestinal lymphocyte activation in

Crohn's disease and ulcerative colitis. A number of workers have demonstrated the increased expression of lymphocyte activation antigens, such as 4F2, transferrin receptor, IL-2 receptor, and HLA-DR in Crohn's disease and ulcerative colitis, whereas other groups have failed to do so. Studies by James and colleagues found that IL-2 mRNA levels were elevated in the mucosa of patients with Crohn's disease but not ulcerative colitis. In contrast, Allison and colleagues demonstrated the appearance of the CD7 activation marker but no increase in IL-2 receptor expression. Studies examining flow cytometric analysis of isolated colonic lamina propria mononuclear cells revealed increased expression of activation markers, including IL-2 receptor, transferrin receptor, and the 4F2 antigen on intestinal B and T cells as well as CD4⁺ and CD8⁺ T lymphocyte subpopulations in both active ulcerative colitis and Crohn's disease. These studies provide evidence that activation of B and T cell lymphocyte populations occur in the intestine as well as in the peripheral blood of patients with IBD.

Figure 2 Cell-mediated immunity in IBD. After luminal bacterial cell wall products lead to macrophage activation, specific antigen presentation occurs, resulting in the activation and expansion of CD4⁺ T helper lymphocytes. The activation of T helper cells leads to enhanced B cell proliferation and maturation, resulting in increased numbers of IgG-producing plasma cells. Resultant secretion of soluble IL-2 receptor by activated mucosal lymphocytes involved in the inflammatory process leads to increased levels of circulating soluble IL-2 receptor, which can be found to correlate with disease activity. In the normal intestine, the predominant immunoglobulin isotype secreted by B cells is IgA, which protects against pathogens by antigen exclusion. IgA overall increase in IgG-secreting lamina propria B cells has been demonstrated. In marked contrast to IgA, IgG is capable of fixing complement, arming NK cells and activating phagocytes. The increase in IgG subclasses is composed primarily of IgG1 and IgG3 in ulcerative colitis, whereas in Crohn's disease the increase is predominantly in IgG1 and IgG2. (Adapted with permission from Screiber S, Raedler A, Stenson WF and MacDermott RP (1992) The role of the mucosal immune system in inflammatory bowel disease. Immunoglobulin synthesis and secretion

Intestinal mononuclear cells from healthy mucosa normally secrete large amounts of IgA. In IBD, IgG cells are increased relative to IgA cells and are present in deeper tissue layers. The mucosal immune system exhibits a markedly heightened IgG immune response because of defective or altered immunoregulation. In IBD, intestinal and peripheral blood mononuclear cells secrete increased immunoglobulin, particularly of the IgG isotype. The greatest increase in spontaneous IgG secretion is seen in ulcerative colitis where intestinal mononuclear cells secrete predominantly IgG1 and IgG3. Crohn's disease intestinal mononuclear cells also exhibit increased IgG1, but secrete IgG2 rather than IgG3 (Figure 2).

The increased secretion of IgG by isolated intestinal mononuclear cells *in vitro* is most likely due to the increased numbers and skewed ratios of intestinal plasma cell populations in IBD. Compared with control specimens, the number of IgG-containing cells is 30 times greater than normal, while the number of IgA-containing cells is double that of normal tissue. There are significantly fewer IgG-containing cells in biopsy specimens of patients with acute infectious colitis when compared to IBD.

IgG1 and IgG3 antibodies, which are increased in ulcerative colitis, are more potent activators of complement and opsonins than are IgG2 and IgG4. They are the major antibodies produced in response to protein antigens. IgG2, on the other hand, is the predominant antibody that responds to carbohydrates and many bacterial antigens. The increased production of IgG2 in Crohn's disease may represent an inappropriate immune response that could partially contain, but not completely eradicate, a chronic infectious process. The delineation and analysis of immunoglobulin isotype regulation may provide important insights into the pathophysiological mechanisms underlying ulcerative colitis and Crohn's disease.

Complement pathway activation

Activation of complement results in the generation of proinflammatory products which may ultimately lead to tissue destruction. Various studies have demonstrated the possible role of complement in tissue damage in ulcerative colitis. Monoclonal antibodies against a neoepitope exclusively expressed by activated C3b and the cytolytically active terminal complement complex have been used to identify potential complement-induced damage in tissue sections from inflamed IBD intestine. Eighty per cent (9 of 11) of patients with ulcerative colitis showed

activated C3b deposited apically on the surface epithelium of involved mucosa. No deposits were seen in 31 matched noninflamed specimens or in 94% (16 of 17) of healthy controls. Strong colocalization of IgG1, activated C3b, and terminal complement complex was shown in 36% (4 of 11) of ulcerative colitis patients. Moreover, increased vascular deposition of terminal complement complexes occurred in both ulcerative colitis and Crohn's disease. Both C3 and C4 levels are elevated in jejunal perfusates of Crohn's disease patients when compared to healthy controls. Complement activation may initiate acute as well as chronic destruction of intestinal tissues and may result in the enhanced activation of granulocytes and macrophages leading to the increased release of potent chemotactic molecules by neutrophils (Figure 3).

Granulocyte and macrophage function

Peripheral blood granulocytes and monocytes isolated and radiolabeled with indium-111 *in vitro* and reinjected into patients, migrate to inflamed areas of the intestine. In one study, more than 90% of radiolabeled phagocytes accumulated rapidly in the inflamed intestine of 91% (20 of 22) of Crohn's disease patients. A further study on 15 patients with ulcerative colitis showed enhanced migration of similar cells into areas of inflamed bowel. The migration of leukocytes from the vascular lumen into the inflamed bowel is mediated through adhesion molecules, particularly LFA-1 (lymphocyte function-associated antigen 1, CD11a), which binds to ICAM-1 (intercellular adhesion molecule 1, CD54). In IBD, the expression of ICAM-1 on endothelial cells is increased and is accompanied by an increase of CD11a on mononuclear phagocytes (Figure 4).

Cytokine production

Inflammatory events are mediated partly through the effects of various cytokines, including IL-1 α , IL-1 β , IL-6, or tumor necrosis factor α (TNF α). Both IL-1 α and IL-1 β induce fever, stimulate acute phase protein synthesis, and activate the immune system. TNF α causes hemodynamic shock and cachexia in a number of disease states. Both TNF α and IL-6 enhance cellular catabolism, induce acute phase proteins, and stimulate pyrogenic activity. TNF α activates endothelial cells and can induce IL-1 and IL-6. Both TNF α and IL-2 stimulate prostaglandin I₂ (PGI₂), PGE₂ and platelet-activating factor (PAF) secretion by cultured endothelial cells.

Levels of IL-1 are increased in inflamed mucosa from patients with both Crohn's disease and ulcer-
